## Dust 1

- Observed Properties
- Dust Materials

# Observed Properties

---

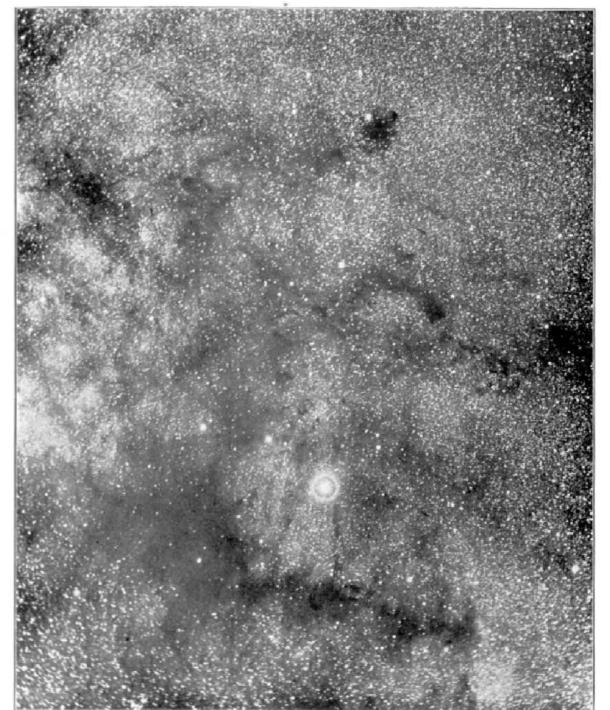

- Observational Evidence on the presence of dust grains in the ISM
  - Wavelength-dependent attenuation (“extinction”) of starlight by absorption and scattering, observable in a wavelength range of  $20\mu\text{m}$  to  $0.1 \mu\text{m}$ . The extinction includes a number of spectral features that provide clues to grain composition.
  - Wavelength-dependent polarization of starlight
  - Scattered light in reflection nebulae
  - Thermal emission from dust, at wavelengths ranging from the sub-mm to  $2\mu\text{m}$ .
  - Small-angle scattering of X-rays, resulting in “scattering halos” around X-ray point sources.
  - Microwave emission from dust, probably from rapidly spinning ultra-small grains.
  - Luminescence when dust is illuminated by starlight — the so-called extended red emission.

- Extinction = Absorption + Scattering
  - Dust particles can scatter light, changing its direction of motion. When we look at a reflection nebula, like that surrounding the Pleiades, we are seeing light from the central stars that has been scattered by dust into our line of sight.
  - Dust particles can also absorb light. The relative amount of scattering and absorbing depends on the properties of the dust grains.
  - When we look at a distant star through the intervening dust, the excess dimming of the star is caused by a combination of scattering and absorbing as extinction.
- Thermal radiation from Dust
  - When dust absorbs light, it becomes warmer, so dust grains can emit light in the form of thermal radiation. Most of this emission is at wavelengths from a few microns (near IR) to the sub-mm range (Far-IR).
- Polarization
  - The polarization of starlight was discovered in 1949 (Hall 1949).
  - The degree of polarization tends to be larger for stars with greater reddening, and stars in a given region of the sky tends to have similar polarization directions.

# Dust matters!

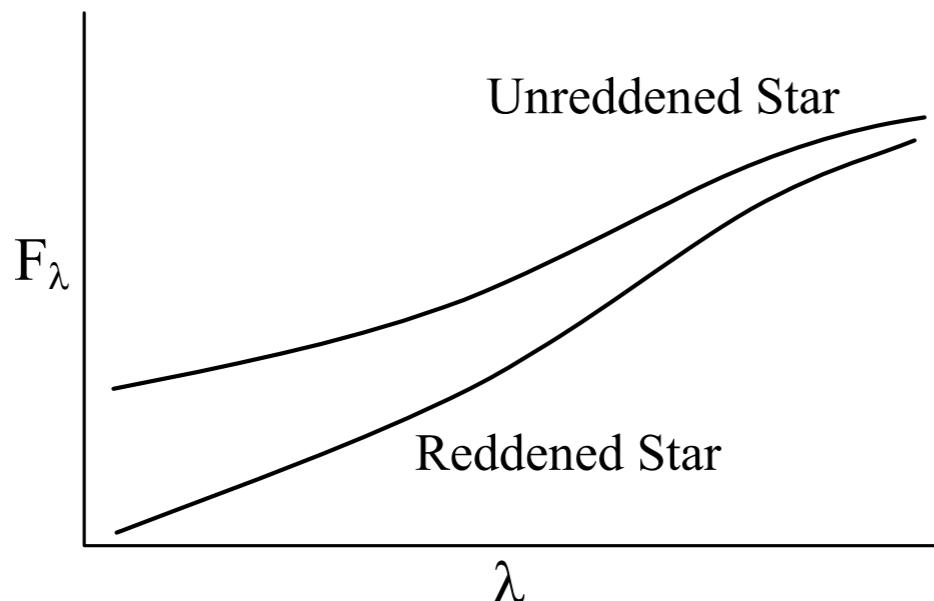

---

- Importance of Dust
  - In our Galaxy, the gas-to-dust ratio is about 100:1 by mass. Since the ISM is about 10% of the baryonic mass of the Galaxy, dust grains comprise roughly 0.1% of the total baryonic mass.
  - Dust grains absorb roughly 30-50% of the starlight emitted by the Galaxy and re-emit it as far-infrared continuum emission. ***This means that only 0.1% of the baryons are ultimately responsible for a third to a half of the bolometric luminosity of the Galaxy.***
  - Dust grains are central to the chemistry of interstellar gas. ***The abundance of H<sub>2</sub> in the ISM can only be understood if catalysis on dust grains is the dominant formation avenue.***
  - The formation of planetary systems is believed to begin when dust grains in a protostellar disk begin to coagulate into larger grains, leading to planetesimals and eventually to planets, carrying their complex organic molecules with them.

# Interstellar Extinction

---

- History - extinction
  - Barnard (1907, 1910) was apparently the first to realize that some stars were dimmed by an “absorbing medium.”
  - Trumpler (1930) showed that the stars in distant open clusters were dimmed by something in addition to the inverse square law, and concluded that interstellar space in the galactic plane contained “fine cosmic dust particles of various sizes... producing the observed selective absorption.”
- Pair method
  - Trumpler compared the spectra of pairs of stars with identical (or similar) spectral type, one with negligible obscuration and the other extinguished by dust along the line of sight. This method remains our most direct way to study the “selective extinction” or “reddening” of starlight by the interstellar dust.

- ▶ Because atomic hydrogen absorbs strongly for  $h\nu > 13.6 \text{ eV}$ , it is possible to measure the contribution of dust to the attenuation of light only at  $h\nu < 13.6 \text{ eV}$  or  $\lambda > 912 \text{ \AA}$ .

- ***Extinction***

- Astronomers characterize the attenuating effects of dust by the “extinction”  $A_\lambda$  at wavelength  $\lambda$ . The extinction at a particular wavelength  $\lambda$ , measured in “magnitudes” is defined by the difference between the observed magnitude  $m_\lambda$  and the unabsorbed magnitude  $m_\lambda^0$ :

$$\begin{aligned} A_\lambda \text{ [mag]} &= m_\lambda - m_\lambda^0 \\ &= -2.5 \log_{10} \left( \frac{F_\lambda}{F_\lambda^0} \right) \end{aligned}$$

$F_\lambda$  = the observed flux from the star

$F_\lambda^0$  = the flux that would have been observed if the only attenuation had been from the inverse square law.

- The extinction measured in magnitudes is proportional to the optical depth:

$$\begin{aligned} A_\lambda &= 2.5 \log_{10} (e^{\tau_\lambda}) = 2.5 \log (e) \times \tau_\lambda \\ &= 1.086 \tau_\lambda \end{aligned}$$

---

- ***The Reddening Law, Extinction Curve***

- Extinction curve - the extinction  $A_\lambda$  as a function of wavelength or frequency
  - ▶ A typical extinction curve shows the ***rapid rise in extinction in the UV.***
  - ▶ ***The extinction increases from red to blue,*** and thus the light reaching us from stars will be “reddened” owing to greater attenuation of the blue light.
  - ▶ The reddening by dust is expressed in terms of a color excess; for instance,

B-V color excess:  $E(B - V) \equiv A_B - A_V$        $\lambda_B \sim 4400 \text{ \AA}$   
 $\lambda_V \sim 5500 \text{ \AA}$

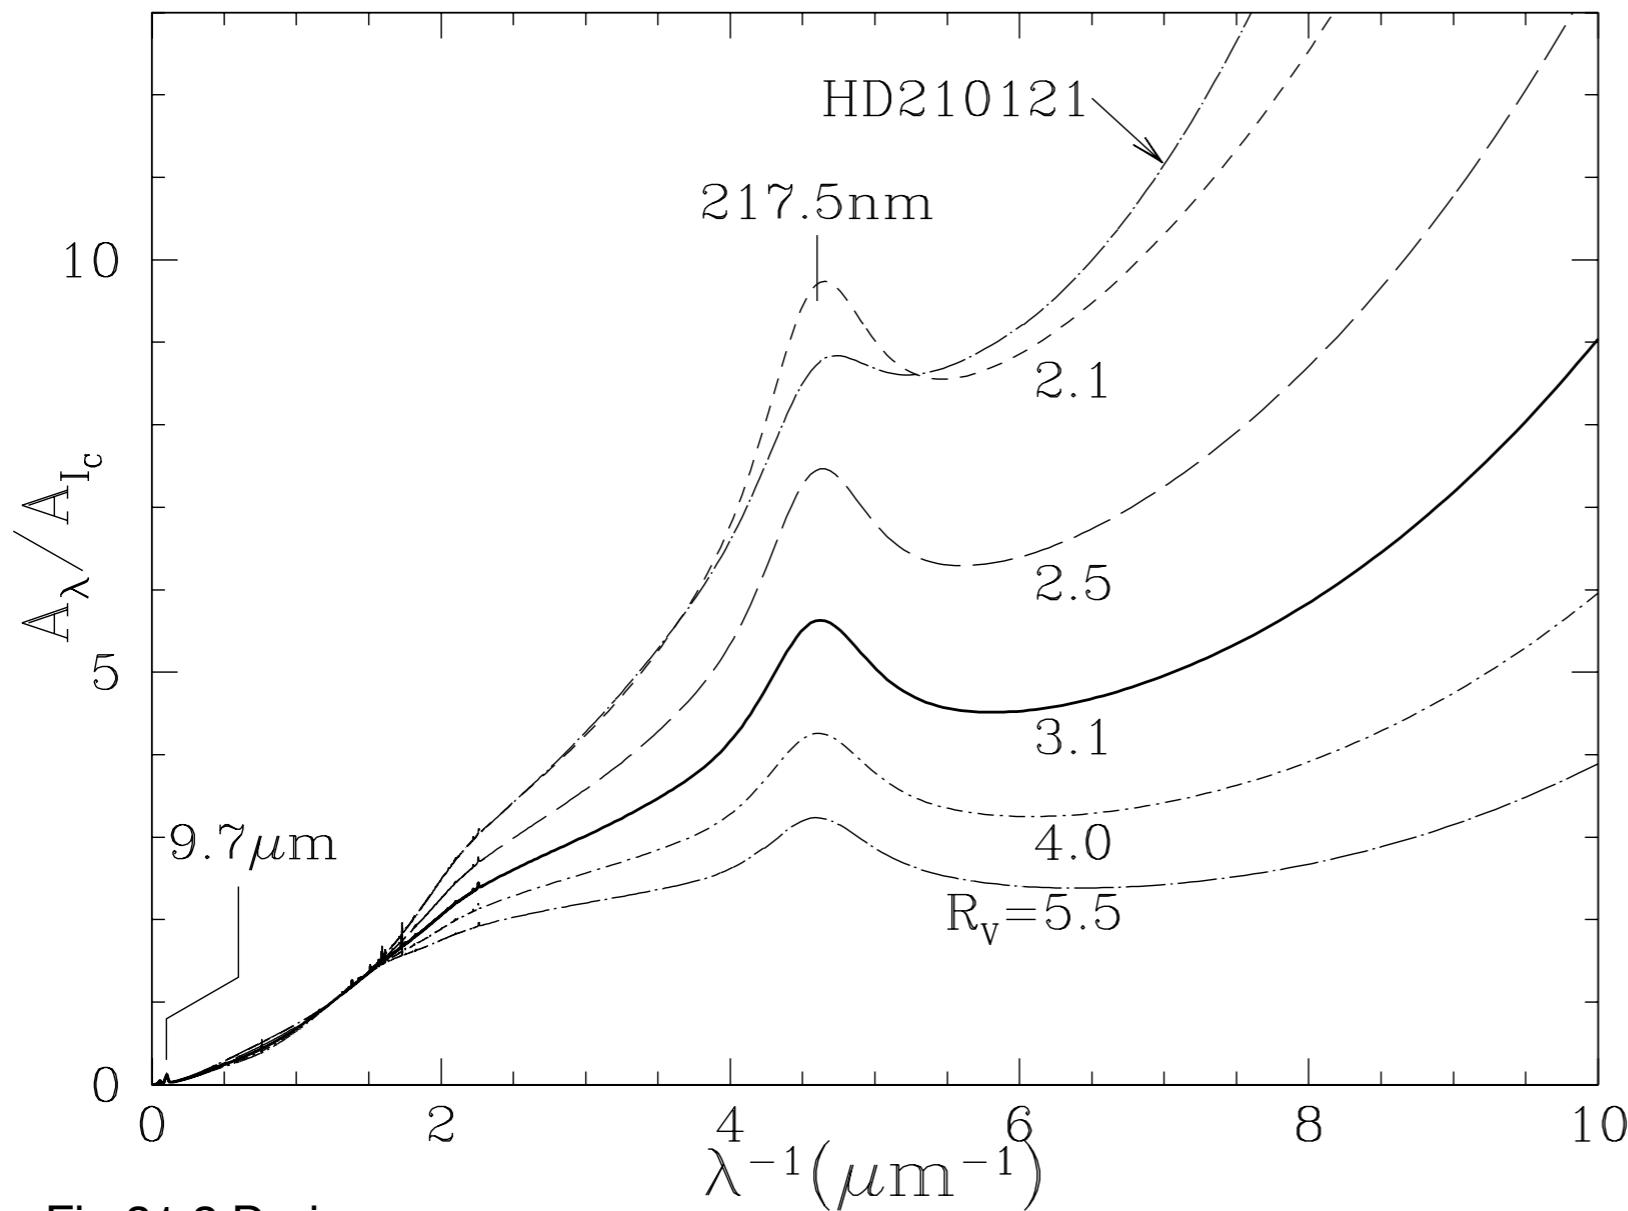

in general,       $E(\lambda_1 - \lambda_2) \equiv A_{\lambda_1} - A_{\lambda_2} \quad (\lambda_1 < \lambda_2)$

- ▶ The detailed wavelength dependence of the extinction - the “reddening law” - is sensitive to the composition and size distribution of the dust particles.
- ▶ The slope of the extinction at visible wavelengths is characterized by the dimensionless ratio, the ratio of total to selective extinction:

$$R_V \equiv \frac{A_V}{A_B - A_V} \equiv \frac{A_V}{E(B - V)}$$

- ▶  $R_V$  ranges between 2 and 6 for different lines of sight. Sightlines through diffuse gas in the Milky Way have  $R_V \approx 3.1$  as an average value. ***Sightlines through dense regions tend to have larger values of  $R_V$ .*** In dense clouds, the value  $R_V \approx 5$  is typically adopted.

- ▶ ***Observed extinction curves vary in shape from one line of sight to another.***
- ▶ Extinction curve, relative to the extinction in the Cousins I band ( $\lambda = 8020\text{\AA}$ ), as a function of inverse wavelength, for Milky Way regions characterized by different values of  $R_V$ .

Cardelli et al. (1989) showed that the optical-UV extinction can be approximated by **a one-parameter family of curves**, parameterized by  $R_V$ ,

$$A_\lambda / A_{\lambda_{\text{ref}}} \approx f_1^{\text{CCM}}(\lambda; R_V)$$

Fitzpatrick (1999) recommends a slightly modified function, which has been used to generate the synthetic extinction curves shown in the left side.

The extinction model was extended into the infrared by Draine (1989).

Note that the extinction curve toward the star HD210121 (with  $R_V = 2.1$ ) differs from the CCM extinction curve for  $R_V = 2.1$ .

- If the dust grains were large compared to the wavelength, we would be in the “geometric optics” limit, and the extinction cross section would be independent of wavelength (gray extinction), with  $R_V = \infty$ .
  - ▶ The tendency of the extinction to rise with decreasing  $\lambda$ , even at the shortest ultraviolet wavelengths tells us that grains smaller than the wavelength must be making an appreciable contribution to the extinction at all observed wavelengths, down to  $\lambda = 0.1\mu\text{m}$ .
  - ▶ As we will see later, “small” means (approximately) that  $2\pi a/\lambda \lesssim 1$ . Thus interstellar dust must include a large population of small grains with  $a \lesssim 0.015\mu\text{m}$ .
- The dust appears to be relatively well-mixed with the gas (Bohlin et al. 1978; Rachford et al. 2009):

$$\frac{N_{\text{H}}}{E(B-V)} = 5.8 \times 10^{21} \text{ H cm}^{-2} \text{ mag}^{-1}$$

$N_{\text{H}} \equiv N(\text{HI}) + 2N(\text{H}_2)$   
column density of total hydrogen nuclei

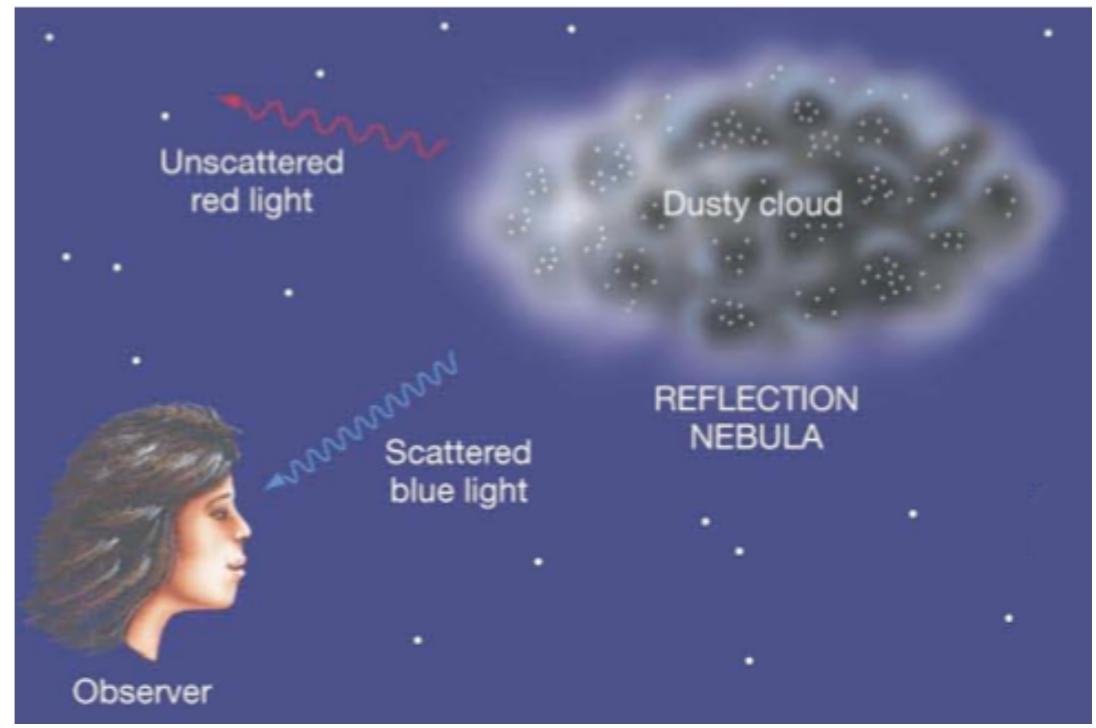

- ▶ For sightlines with  $R_V \approx 3.1$ , this implies that

$$\frac{A_V}{N_{\text{H}}} \approx 5.3 \times 10^{-22} \text{ mag cm}^2 \text{ H}^{-1}$$

- ▶ Thus, even at high galactic latitudes, where the column density of hydrogen is  $\sim 10^{20} \text{ cm}^{-2}$ , there is still some foreground extinction when looking at extragalactic sources;  $\sim 0.05$  magnitudes in the V band.

## • ***Scattering of Starlight***

- When an interstellar cloud happens to be unusually near one or more bright stars, we have a reflection nebula, where we see starlight photons that have been scattered by the dust in the cloud.
- ***The spectrum of the light coming from from the cloud surface shows the stellar absorption lines***, thus demonstrating that scattering rather than some emission process is responsible.
- Given the typical size of interstellar dust grains, blue light is scattered more than red light. ***A reflection nebulae is typically blue*** (so for the same reason that the sky is blue, except it's scattering by dust (for the reflection nebula) vs by molecules (for the earth's atmosphere)).
- By comparing the observed scattered intensity with the estimated intensity of the starlight incident on the cloud, it is possible to infer the albedo of the dust - the ratio of scattering cross section to extinction cross section.

## ***Diffuse Galactic Light (DGL)***

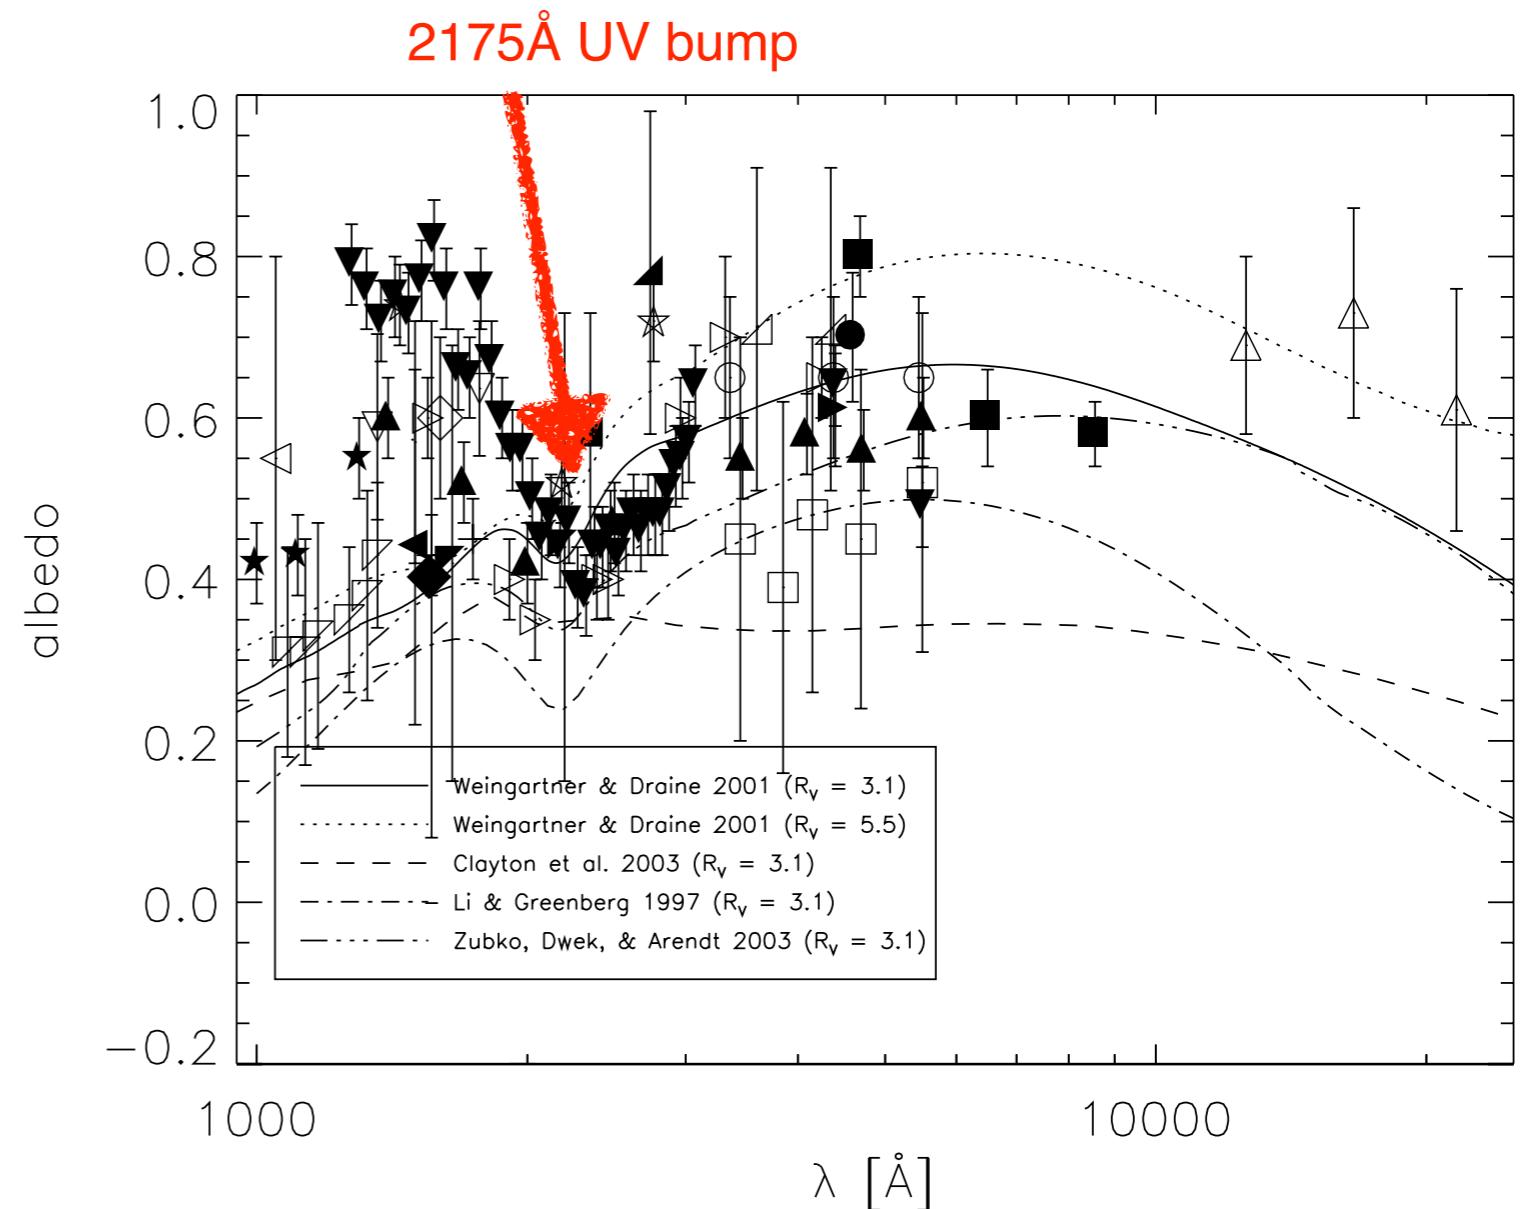

- The term DGL denotes the diffuse component of the galactic background radiation which is produced by scattering of stellar photons by dust grains in interstellar space.
- The DGL is most intense in directions where the dust column density and the integrated stellar emissivity are both high.

- The study of dust scattering properties has shed light on the nature of the 2175Å bump and the far-ultraviolet rise features of extinction curves.
- Lillie & Witt (1976) and Calzetti et al. (1995) showed that the 2175Å bump was likely an absorption feature with no scattered component.
- The current data indicates the wavelength dependence of the albedo is  $\sim 0.6$  in the NIR/optical with a dip to  $\sim 0.4$  for 2175Å bump, a rise to  $\sim 0.8$  around 1500Å, and a drop to  $\sim 0.3$  by 1000Å.

The determinations of the albedo in reflection nebulae, dark clouds, and the DGL are plotted versus wavelength.

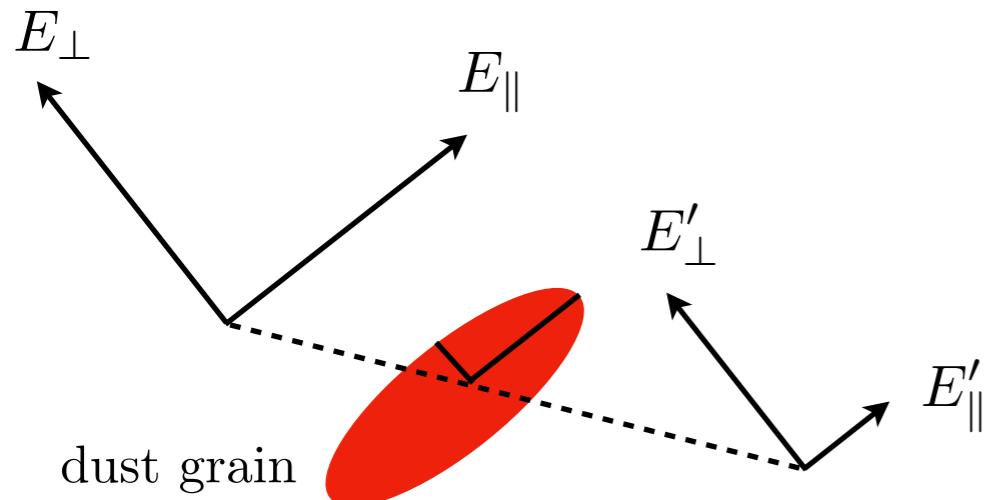

Predictions from dust grain models are also plotted for comparison.

Karl D. Gordon,  
2004, ASPC, 309, 77

- **Polarization of Starlight by Interstellar Dust**

- Initially unpolarized light propagating through the ISM becomes linearly polarized as a result of preferential extinction of one linear polarization mode relative to the other.

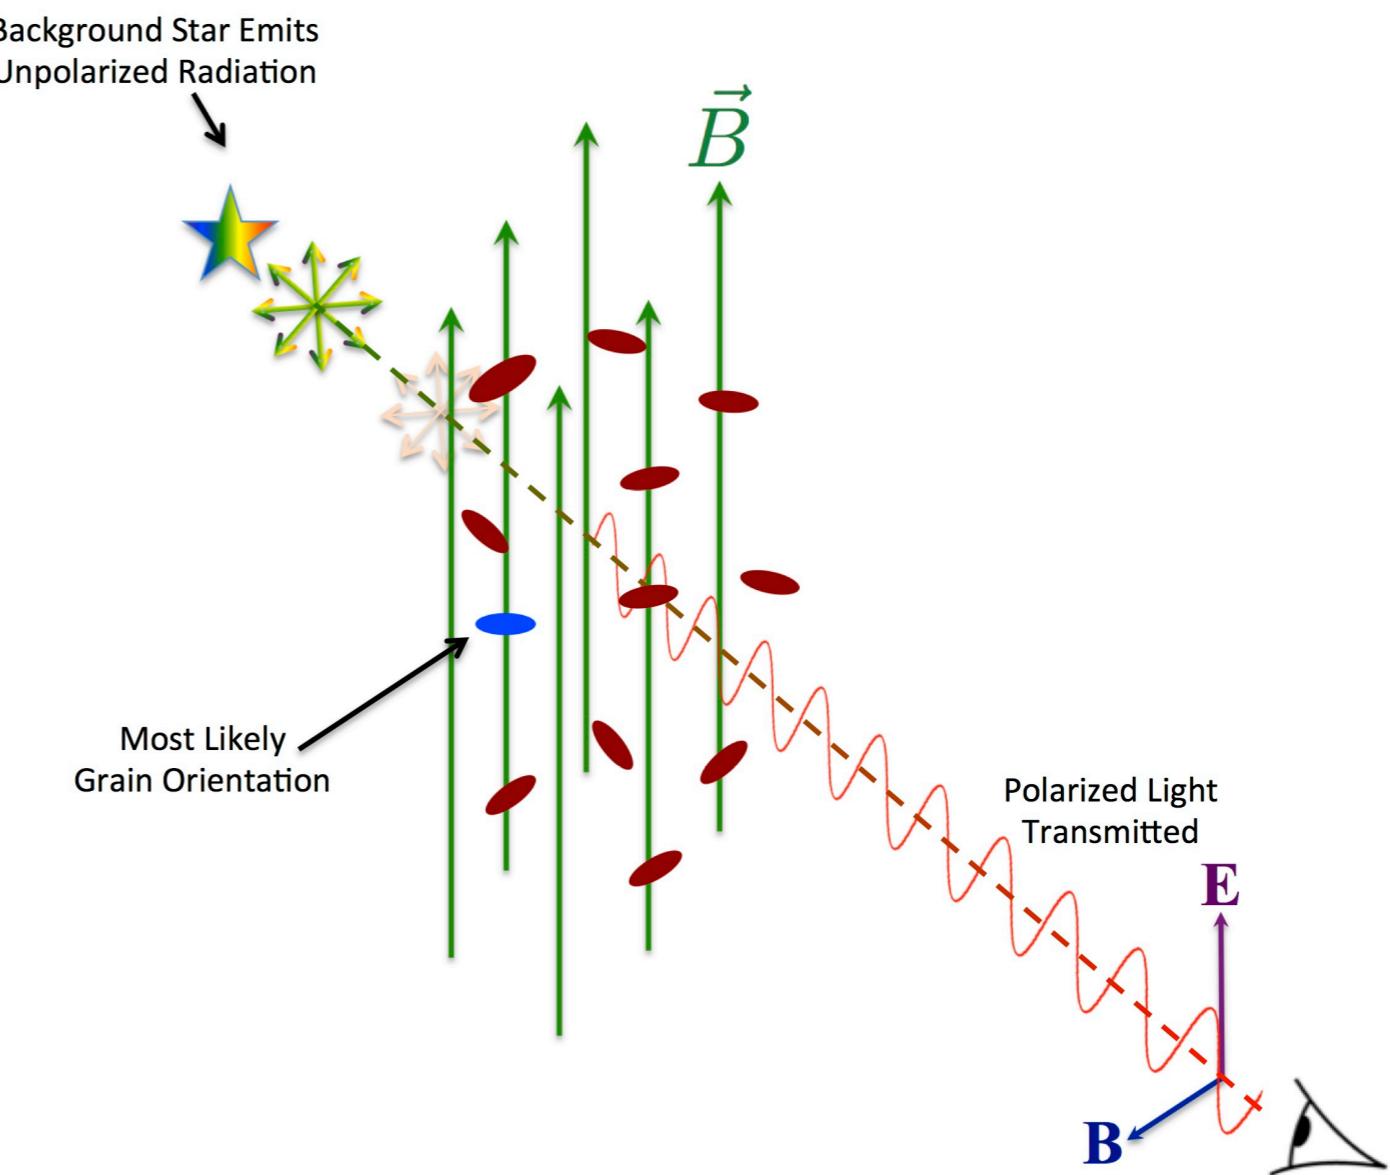

$$E_{\parallel} = E_{\perp}$$

$$E'_{\parallel} < E'_{\perp}$$

$$E'_{\parallel} = E_{\parallel} e^{-\tau_{\parallel}}$$

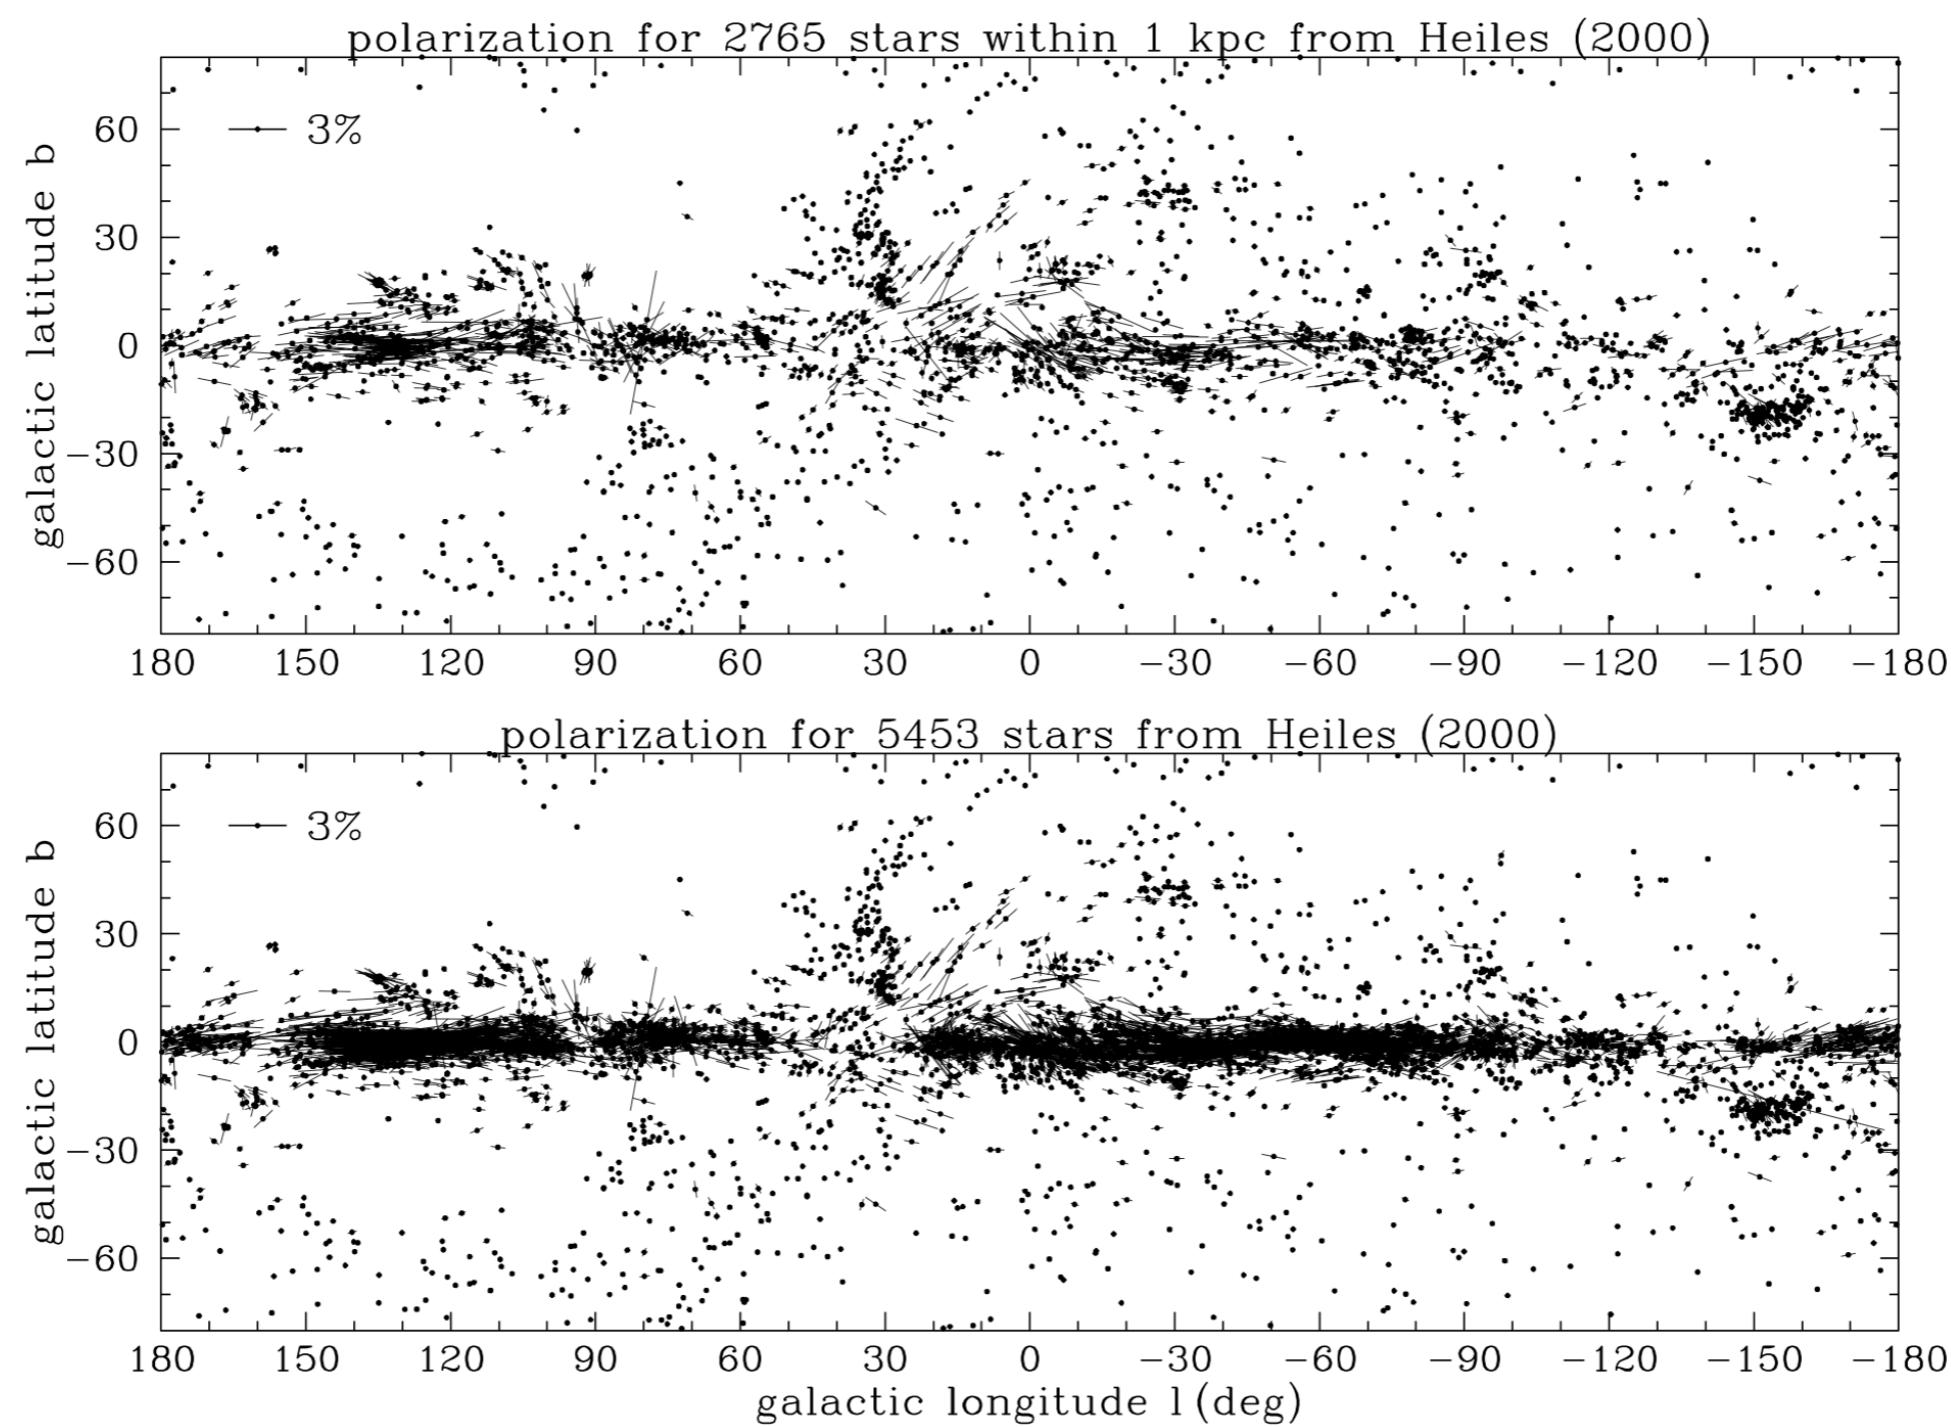

$$E'_{\perp} = E_{\perp} e^{-\tau_{\perp}}$$

$$\tau_{\parallel} > \tau_{\perp}$$

The starlight is slightly more blocked along the long axis of the grains than along the short axis. This give rise to the polarization of starlight.

credit: B-G Andersson

[Fig 21.3, Draine; Heiles (2000)]

- The polarization percentage typically peaks near the V band (5500Å), and can be empirically described by the “**Serkowski law**” (Serkowski 1973):

$$p(\lambda) \approx p(\lambda_{\max}) \exp [-K \ln^2(\lambda/\lambda_{\max})]$$

$\lambda_{\max}$  = the wavelength of the maximum polarization

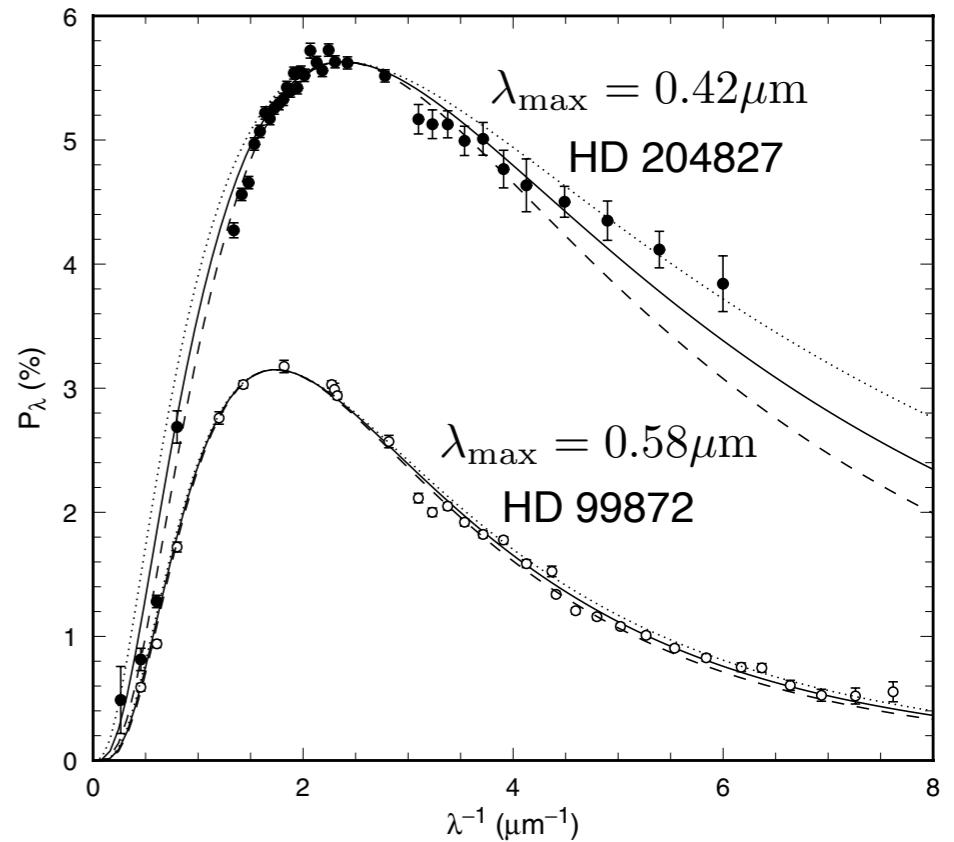

$$K = 1.86(\lambda_{\max}/\mu\text{m}) - 0.1$$

$$\lambda(\mu\text{m}) \approx (0.17 \pm 0.05)R_V$$

$$0.34\mu\text{m} \lesssim \lambda_{\max} \lesssim 1\mu\text{m}, \quad \langle \lambda_{\max} \rangle \approx 0.55\mu\text{m}$$

$$0 < p_{\max} \leq 0.09 \left[ \frac{E(B-V)}{\text{mag}} \right] \approx 0.03 \left[ \frac{A_V}{\text{mag}} \right] \approx 0.03\tau_V$$

[Fig 4.7, Whittet, Dust in the Galactic Environment]

- The reason that the light becomes polarized is that some fraction of the dust grains are elongated and that their long axes line up in the same direction. When they do, the light is slightly more blocked along the long axis of the grains than along the short axis - and polarization results.
- The polarization is produced by dust grains that are somewhat partially aligned by the interstellar magnetic field. The grains are appeared to be aligned with their shortest axes tending to be parallel to the magnetic field direction.
- The decline of polarization towards the UV reflects that small grains apparently do not contribute appreciably to the polarization, either because they are more spherical or because they are not well aligned.

- **Polarized Infrared Emission**

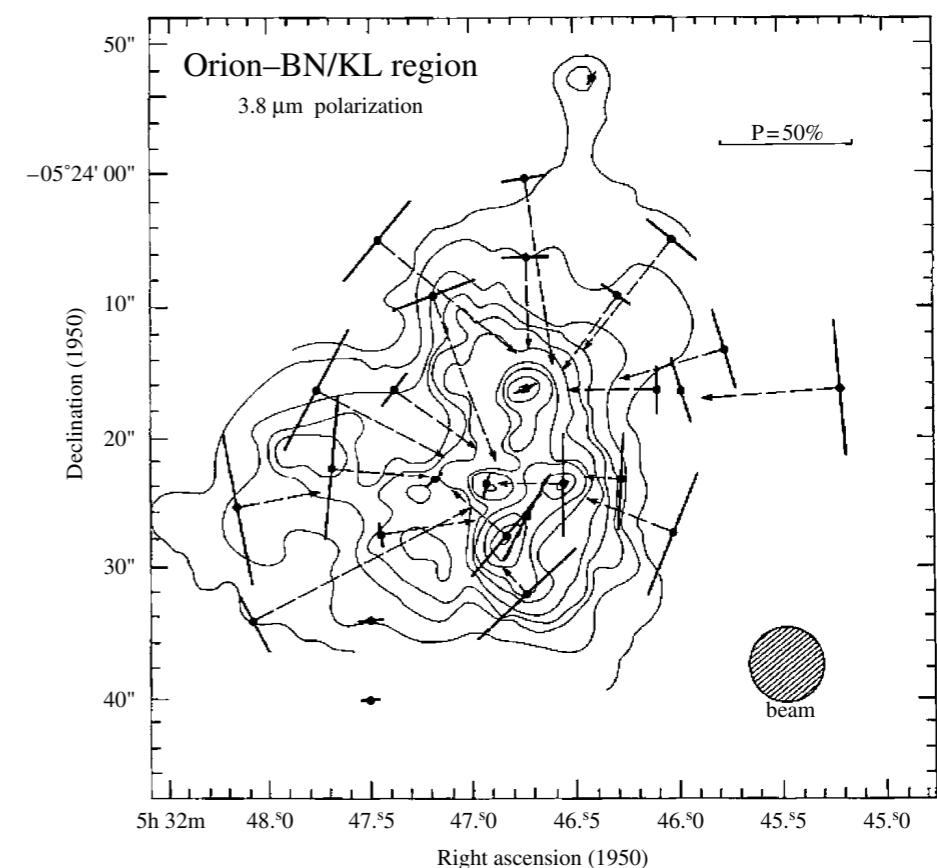

- The far-IR emission from aligned dust grains will also be polarized, this time with a direction along the long axis of the grains. Far-IR polarization has been observed for a large number of molecular clouds that have “high” dust emission optical depths at long wavelengths ( $\sim 0.1\text{-}1$  mm).

- **Polarization due to scattering**

- Scattering of light by dust grains generally also lead to polarization.
- For single scattering, the polarization vector is perpendicular to the line connecting the light source and the scattering grain.
- The degree of polarization and its distribution provide information on the characteristics of the scattering grains and the geometry of the nebula.

Linear polarization of the IR reflection nebula associated with the region of massive star formation in Orion. The linear polarization vectors measured at K are superimposed on a map of the scattered light intensity.

[Werner et al. 1983, ApJ, 265, L13]

# Luminescence

---

- **Extended Red Emission (ERE)**
  - Many dusty objects — including the diffuse ISM, dark clouds, reflection nebulae, post-AGB objects, planetary nebulae, HII regions, and starburst galaxies — show a broad ( $\Delta\lambda = 600-1000\text{\AA}$ ), featureless emission band in the red part of the spectrum (6000-8000 $\text{\AA}$ ). This is called extended red emission (ERE).
  - The ERE cannot be due to thermal emission but rather represents a luminescence process whereby an absorbed UV or visible photon is down-converted to the ERE range.
  - Various forms of carbonaceous materials and crystalline silicon nanoparticles have been proposed as carriers of ERE. In particular, Witt et al. (1998) and Ledoux et al. (1998) suggested **crystalline silicon nanoparticles with 15-50 $\text{\AA}$  diameters** as the carrier on the basis of experimental data showing that silicon nanoparticles could provide a close match to the observed ERE spectra and satisfy the quantum efficiency requirement.
- What is (photo)luminescence?
  - **Luminescence** (냉광) is any emission of light from a substance that does not arise from heating. **Incandescence** (백열광) is light emission due to the elevated temperature of a substance, such as a glowing hot ember.
  - **(Photo)luminescence** is the emission of light from a material following the absorption of light (photo-excitation).
  - **Fluorescence** (형광) is prompt (photo)luminescence that occurs very shortly after photo-excitation of a substance, while **phosphorescence** (인광) is long-lived (photo)luminescence that continues long after the photo-excitation has ceased.

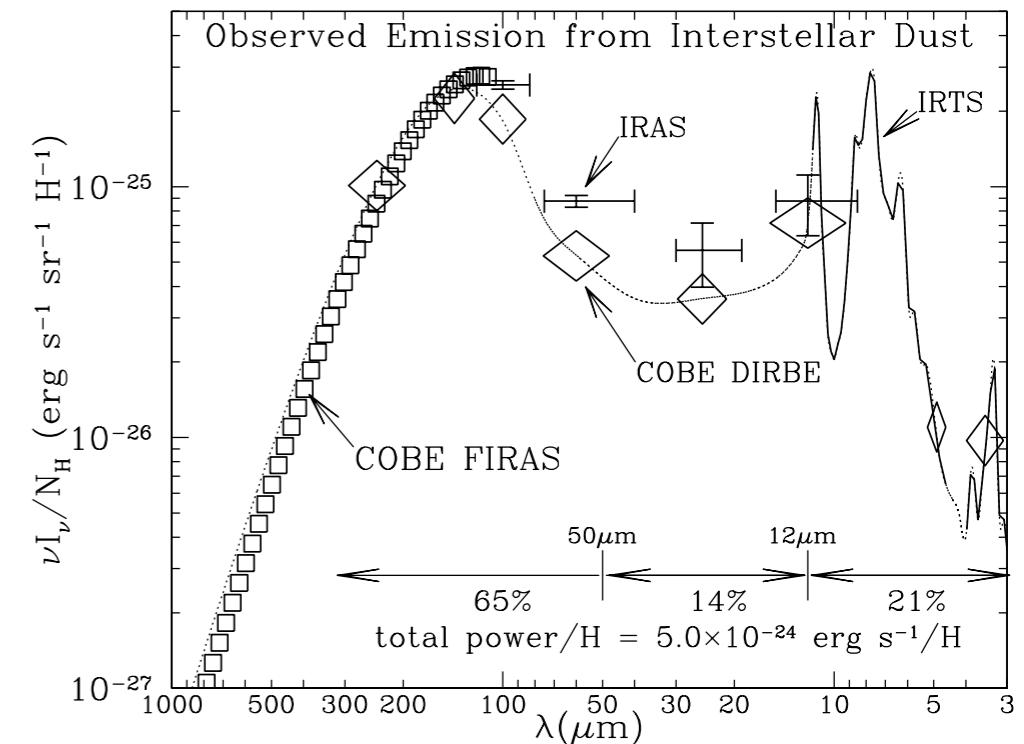

# Infrared Emission

- ***Infrared Emission***

- Dust grains are heated by starlight, and cool by radiating in the infrared.
- Along a typical line of sight through our galaxy, the ratio of dust IR emission to the hydrogen column density tells us the IR luminosity per hydrogen nucleus:

$$\frac{I_{\text{IR}}}{N_{\text{H}}} = 5 \times 10^{-24} \text{ erg s}^{-1}$$

- The IR spectrum provides very strong constraints on grain models.
- There are two components: ***a cold ( $T \sim 15\text{-}20 \text{ K}$ ) component*** emitting mainly at long wavelengths (far-IR) and ***a hot ( $T \sim 500 \text{ K}$ ) component*** dominating the near- and mid-IR emission.
  - ▶ The cold component is due to large dust grains in radiative equilibrium with the interstellar radiation field.
  - ▶ The hot component is due to ultra small grains and PAH species that are heated by a single UV photon to temperatures of  $\sim 1000 \text{ K}$  and cool rapidly in the near- and mid-IR.

Observed IR emission per H nucleon from dust heated by the average starlight background in the local Milky Way.

[Fig 21.6 Draine]

# What is the dust grains made of?

---

- Observational Constraints
  - **Interstellar Depletion:** Certain elements appears to be underabundant or “depleted” in the gas phase. The observed depletions tell us about the major elemental composition of interstellar dust.
  - **Spectroscopy:** We would observe spectroscopic features that would uniquely identify the materials, and allow us to measure the amounts of each material present. But, it is difficult to apply this approach to solid materials because: (1) the optical and UV absorption is largely a continuum; and (2) the spectral features are broad, making them difficult to identify conclusively.
  - **Extinction:**
    - ▶ The wavelength dependence of the extinction curve provides constraints on the interstellar grain size distribution.
    - ▶ What materials could plausibly be present in the ISM in quantities sufficient to account for the observed extinction? A Kramers-Kronig integral over the observed extinction indicates that the total grain mass relative to total hydrogen mass:

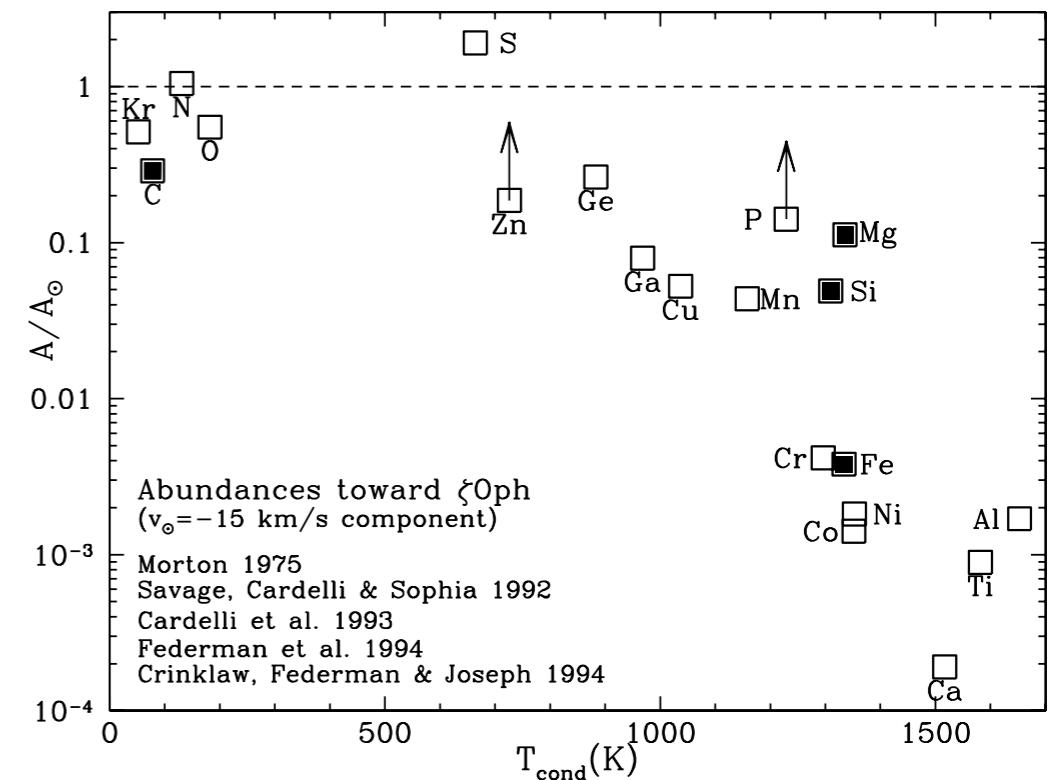

$$M_{\text{dust}}/M_{\text{H}} \gtrsim 0.0083$$

# Interstellar Depletion

- Condensable elements:
  - ▶ Hydrogen: There is no way to have hydrogen contribute appreciably to the grain mass (even polyethylene ( $\text{CH}_2$ )<sub>n</sub> is 86% carbon by mass).
  - ▶ The noble gases (He, Ne, Ar, Kr, Xe...) and nitrogen(N), zinc (Zn), and sulfur (S) are examples of species that generally form only rather volatile compounds. They are observed to be hardly depleted at all.
  - ▶ The only way to have a dust/H mass ratio of 0.0056 or higher is to build the grains out of the most abundant condensable elements: C, O, Mg, Si, S, and Fe (refractory materials; 내열성물질).

- Abundance Constraints toward  $\zeta$  Oph

- ▶ Nitrogen is present at its solar abundance.
- ▶ C abundance is at  $\sim 35\%$  of its solar value.
- ▶ O abundance is at  $\sim 55\%$  of its solar value.
- ▶ Mg is at  $\sim 11\%$ .
- ▶ Si is at  $\sim 5\%$ .
- ▶ Fe is at  $\sim 0.4\%$ .

Gas-phase abundances (relative to solar) in the diffuse cloud toward  $\zeta$  Oph, plotted versus “condensation temperature”

- With the elements providing the bulk of the grain volume identified, we can limit consideration to the following possible materials:
  - Silicates
    - ▶ pyroxene composition  $Mg_xFe_{1-x}SiO_3$  ( $0 \leq x \leq 1$ )
    - ▶ olivine composition  $Mg_{2x}Fe_{2-2x}SiO_4$  ( $0 \leq x \leq 1$ )
  - Oxides of silicon, magnesium, and iron (e.g.,  $SiO_2$ ,  $MgO$ ,  $Fe_3O_4$ )
  - Carbon solids (graphite, amorphous, and diamond)
  - Hydrocarbons (e.g., polycyclic aromatic hydrocarbons)
  - Carbides, particularly silicon carbide ( $SiC$ )
  - Metallic Fe
  - Other elements (e.g., Ti, Cr, Al, and Ca) are also present in interstellar grains, but because of their low abundances, they contribute only a minor fraction of the grain mass.

# Extinction Curve - The sizes of Interstellar Grains

- The extinction keeps rising throughout the IR, visible and near- and far-UV wavelength range.
  - Babinet's theorem:** Since extinction “saturates” when the grain size becomes comparable to or bigger than the wavelength ( $a \gtrsim \lambda$ ), interstellar grains have to span a range of sizes.
  - Mie theory:** The extinction at wavelength  $\lambda$  is mainly due to a grain size  $a \sim \lambda/2\pi$ .
    - The visible extinction is then due to grains with a typical size of 2000Å.
    - The UV extinction, on the other hand, reflects the presence of grains with sizes in the range of 50-200Å.

- Size of dust grains:

$$\frac{A_V}{N_{\text{H}}} = 1.086 \frac{\tau_V}{N_{\text{H}}} = 1.086 \frac{n_{\text{d}} C_{\text{ext}}(\lambda_V)}{n_{\text{H}}}$$

assuming

$$C_{\text{ext}} \approx \pi a^2 \implies$$

$$\frac{A_V}{N_{\text{H}}} \approx 5.3 \times 10^{-22} \text{ mag cm}^2 \text{ H}^{-1}$$

$$\frac{n_{\text{d}}(a)}{n_{\text{H}}} \approx \frac{A_V/N_{\text{H}}}{1.086(\pi a^2)} \approx \frac{4.88 \times 10^{-22}}{\pi(a/\text{cm})^2}$$

- Ascribing the observed visual extinction per H to  $\sim 2000\text{\AA}$  grains implies an abundance of such grains of  $\sim 4 \times 10^{-13}$ .
- Similarly, the 10 times higher FUV extinction per H atom results in an abundance of  $\sim 100\text{\AA}$  grains of  $2 \times 10^{-9}$ .

# Observed Spectral Features of Dust

---

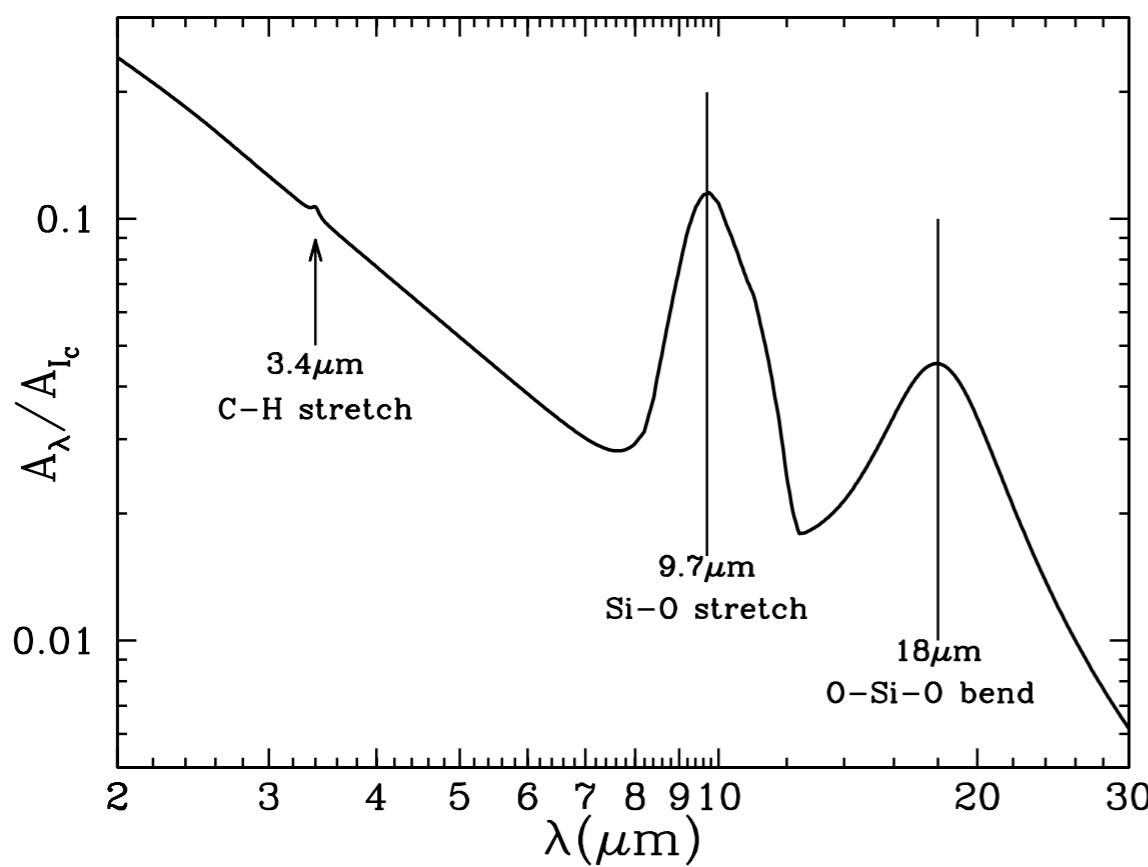

- The 2175Å Feature (UV bump)

- The strongest feature in the interstellar extinction curve is a broad “bump” centered at  $\sim 2175\text{\AA}$  where there is additional absorption above the rough  $1/\lambda$  behavior at adjacent wavelengths.
  - ▶ The feature is well-described by a Drude profile.

$$S(\lambda) = \frac{2}{\pi} \frac{\gamma_0 \lambda_0 \sigma_{\text{int}}}{(\lambda/\lambda_0 - \lambda_0/\lambda)^2 + \gamma_0^2} \quad \text{where } \sigma_{\text{int}} = \int S(\lambda) d\lambda^{-1}$$

- ▶ The central wavelength is nearly identical on all sightlines, but the width varies significantly from one region to another.
- ▶ The strength of the feature is a strong function of the metallicity of the gas, with the UV bump appearing slightly weaker in the LMC extinction curve (metallicity  $\sim 50\%$  solar), but essentially absent in the SMC extinction curve (metallicity  $\sim 10\%$  solar).
- The strength of this feature implies that the responsible material must be abundant: it must be made of H, C, N, O, Mg, Si, S, or Fe.
- Small graphite grains would have a strong absorption peak at about this frequency, due to  $\pi \Rightarrow \pi^*$  electronic excitations in the  $\text{sp}^2$ -bonded carbon sheets.
  - ▶ It seems most likely that the 2175Å feature is due to some form of  $\text{sp}^2$ -bonded carbon material.
  - ▶ This is generally attributed to particles rich in carbon, either in the form of graphite, hydrogenated amorphous carbon grains, or various aromatic forms of carbon, but models have not yet succeeded in reproducing all the details (the width of the feature).
- Alternatives have been suggested. OH- on small silicate grains.

- Mid-Infrared Silicate Features:
  - There is a conspicuous IR absorption feature at  $9.7\mu\text{m}$ . Silicate minerals generally have strong absorption responses due to the Si-O stretching mode near  $10\mu\text{m}$ .
  - It seems virtually certain that the interstellar  $9.7\mu\text{m}$  feature is due to silicates. This conclusion is strengthened by the fact that the  $10\mu\text{m}$  emission feature is seen in the outflows from oxygen-rich stars (which would be expected to condense silicate dust) but not in the outflows from carbon-rich stars.
  - Near  $18\mu\text{m}$ , interstellar dust shows another feature, attributable to the Si-O-Si bending mode in amorphous silicates.

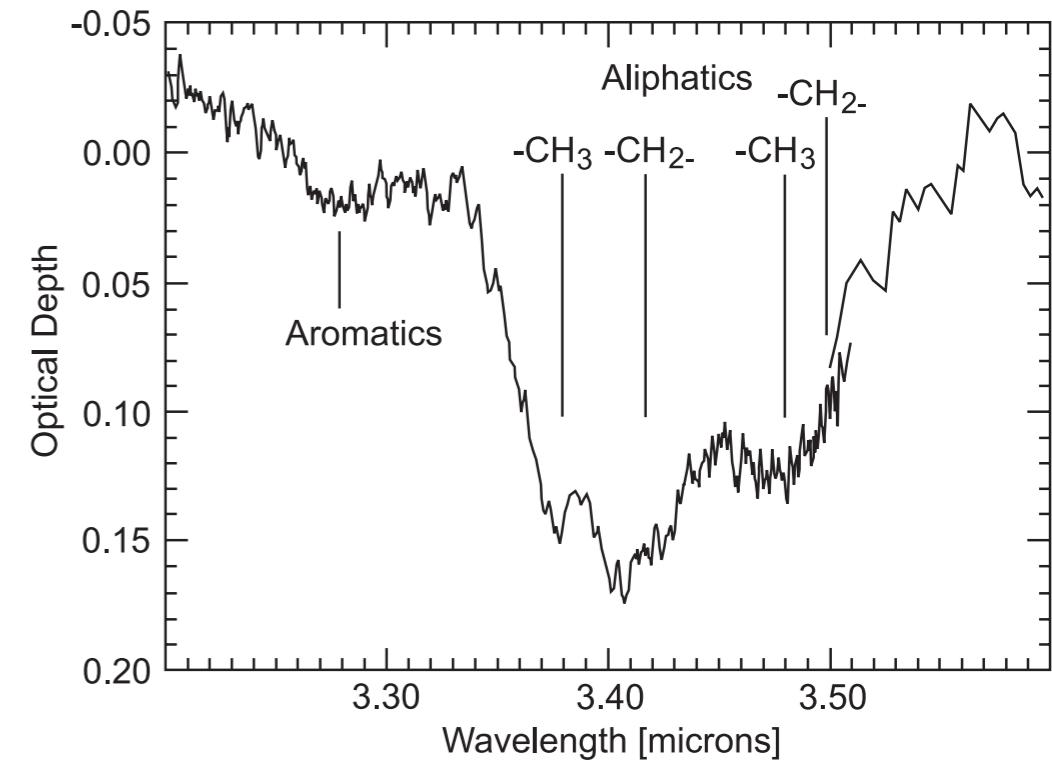

The fact that the  $9.7\mu\text{m}$  band is fairly featureless, unlike what is seen in laboratory silicate crystals, suggests that this “astrophysical” silicate is primarily amorphous rather than crystalline in nature.

IR extinction curve.  
[Fig 23.2 Draine]

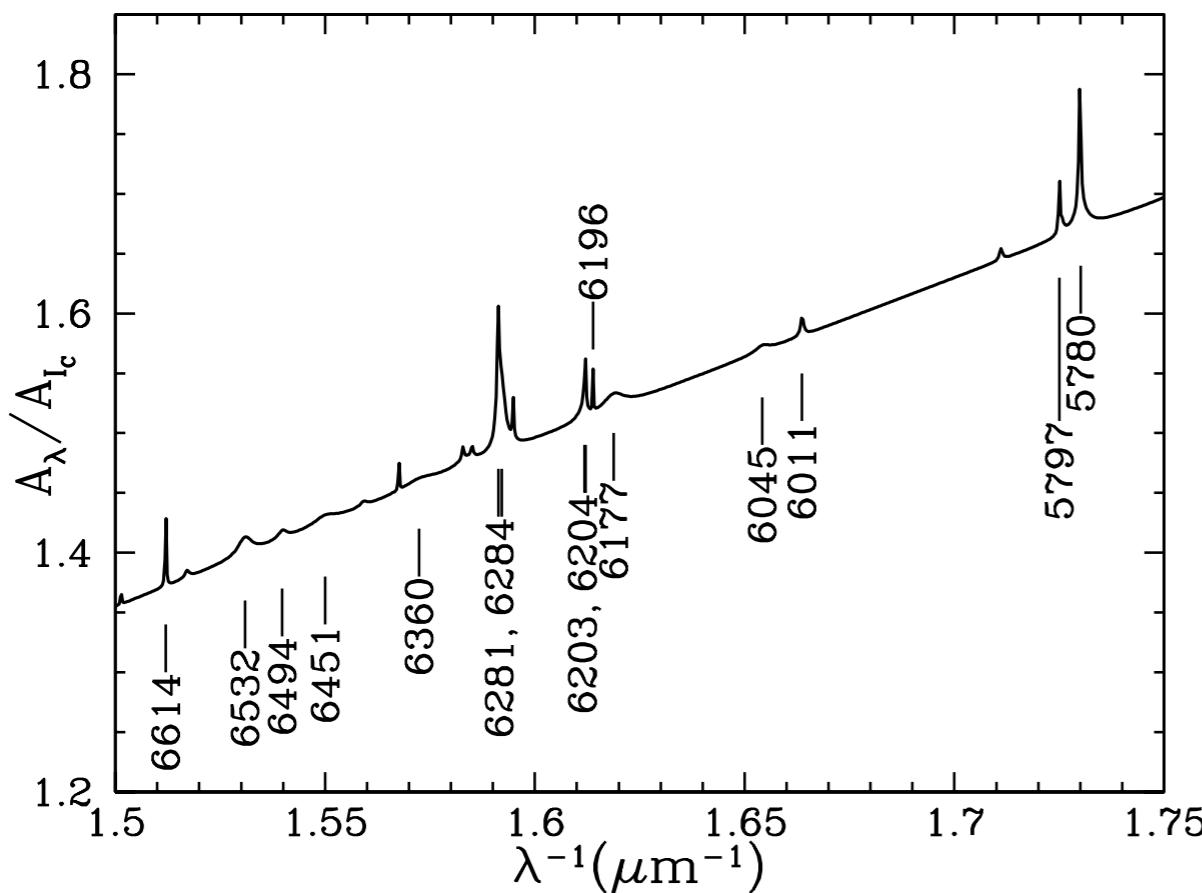

- The  $3.4\mu\text{m}$  Feature

- There is a broad absorption feature at  $3.4\mu\text{m}$  that is almost certainly due to the C-H stretching mode in “aliphatic” hydrocarbons (organic molecules with carbon atoms joined in straight or branched chains).
- The  $3.4\mu\text{m}$  C-H feature is found to be weaker (relative to the overall extinction) in dark clouds than in diffuse clouds (Shenoy et al. 2003), which has been interpreted as evidence that the C-H bonds responsible for the  $3.4\mu\text{m}$  feature are destroyed in molecular clouds, perhaps as the result of cosmic ray irradiation, and regenerated when carbonaceous grains are exposed to atomic hydrogen in diffuse clouds.
- Aromatic/aliphatic ratio:
  - ▶ Pendleton & Allamandola (2002) concluded that the carbonaceous material was  $\sim 85\%$  aromatic (ring) and  $\sim 15\%$  aliphatic.
  - ▶ However, Dartois et al. (2004) concluded that at most  $15\%$  of the carbon is aromatic.
  - ▶ The aromatic/aliphatic ratio remains uncertain.

The source GCS3 in the  
Galactic Center  
Chiar et al. (2000, ApJ)

- Diffuse Interstellar Bands
  - There are numerous web, very broad ( $\text{FWHM} > 140\text{\AA}$ ) features, known as the diffuse interstellar bands or DIBs, at visible wavelengths.
  - These features are too broad to be absorption lines of atoms, ions, or small molecules. The strengths of DIBs are in general correlated with dust extinction, so it is likely that the DIBs are associated with the dust grain population.
  - The first DIBs were discovered 98 years ago (Heger 1922) and their interstellar nature was established 86 years ago (Merrill 1934).
  - ***However, not a single one of the DIBs has been convincingly identified!***

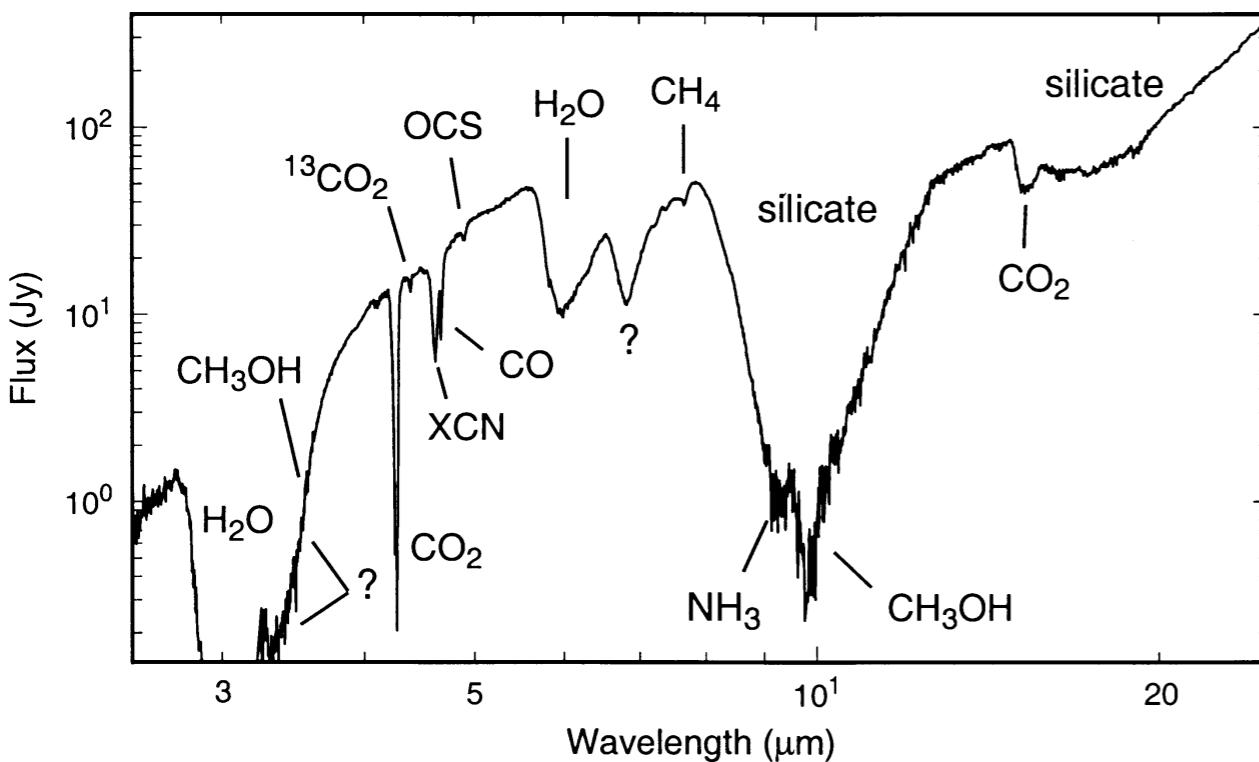

Some of the DIBs may be due to free-flying large molecules (i.e., ultrasmall dust grains).

Extinction curve, showing some of the DIBs

Fig 23.3 Draine

- Ice Features in Diffuse and Dark Regions

- In dark molecular clouds, a number of absorption features appear, most notably a strong band at  $3.1\mu\text{m}$  which is produced by the O-H stretching mode in  $\text{H}_2\text{O}$  ice.
- A number of other absorption features are also seen, including features due to CO ( $4.67\mu\text{m}$ ),  $\text{CH}_3\text{OH}$  ( $3.53\mu\text{m}$ , methanol), and  $\text{CO}_2$  ( $15.2\mu\text{m}$ ).
- These are generally thought to arise in icy “mantles” that encase dust grains found in dense molecular clouds. Ice mantles are not found on grains in the general ISM, as exposure to the interstellar radiation field sublimes the ices.
- CO is a molecule most commonly observed in the gas phase, but it can condense as a “frost” onto dust grains when the temperature drops below  $\sim 17\text{K}$ .  $\text{CO}_2$  has not yet positively observed in the gas phase (despite numerous searches) but it is seen as an ice condensed onto grains surfaces.

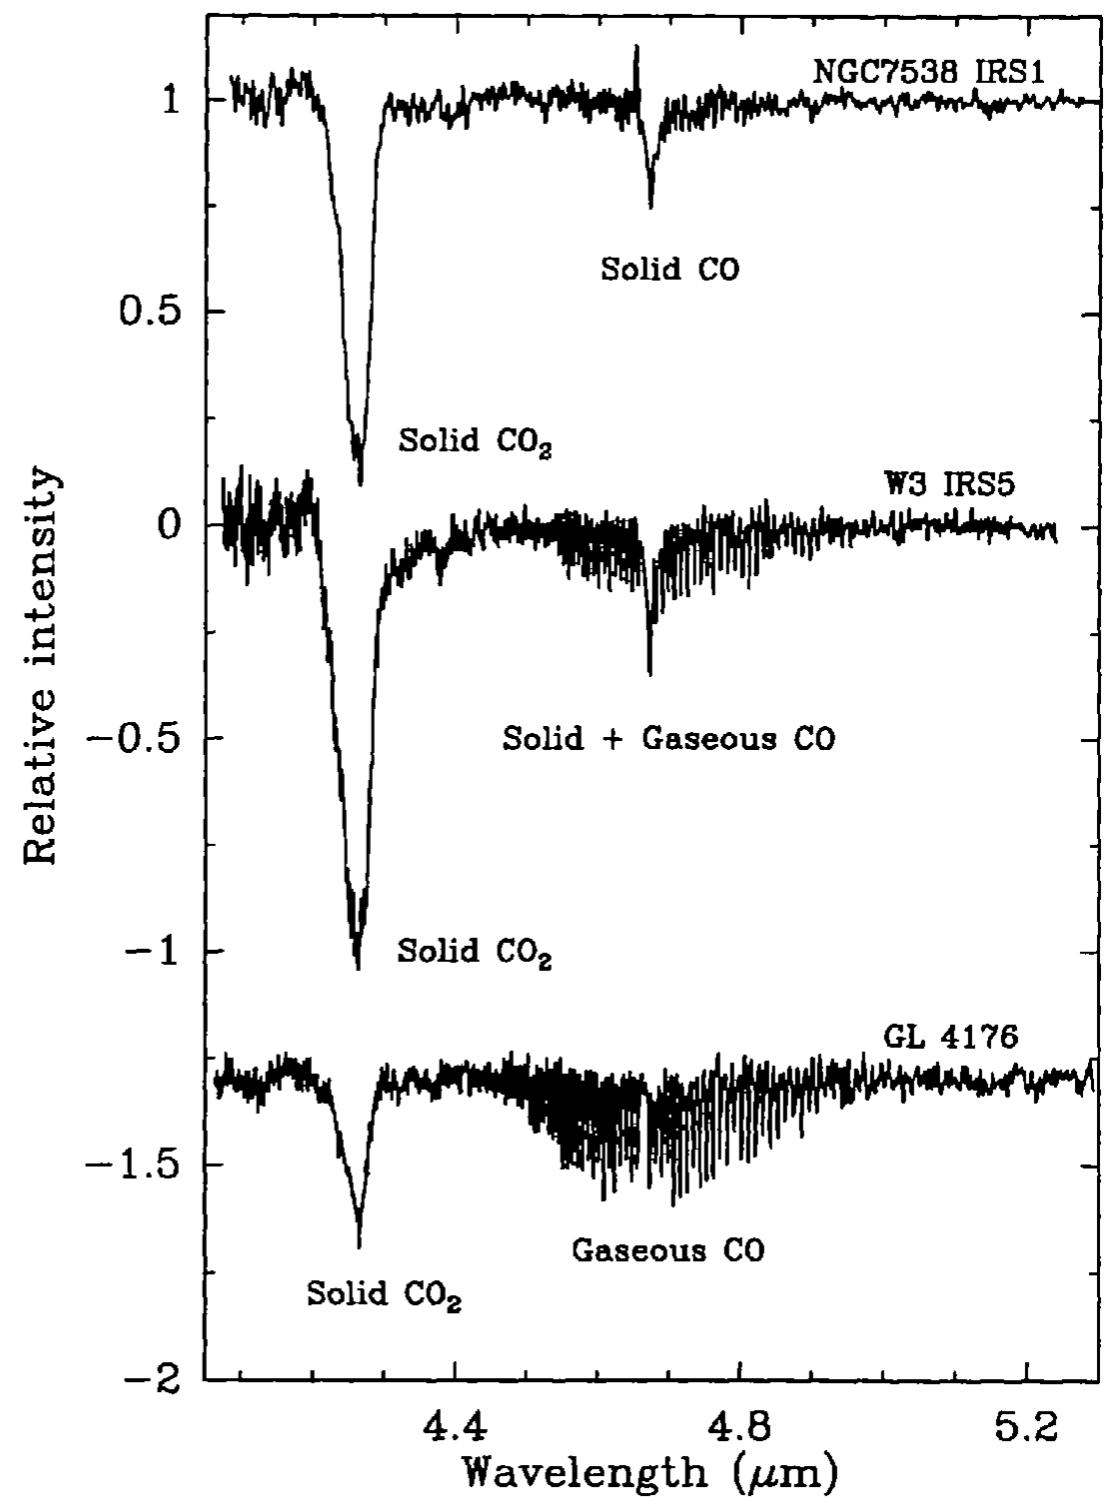

Spectrum of the dust-embedded young stellar object W33A.

An ice feature called XCN at  $4.62\mu\text{m}$  is attributed to  $\text{C} \equiv \text{N}$  bonds, but the “X” carrier is so far unidentified.

Gibb et al. (2000, ApJ)

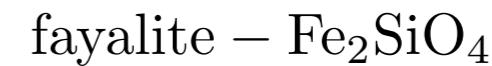

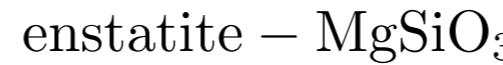

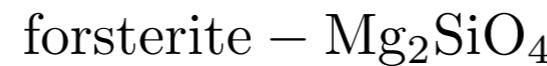

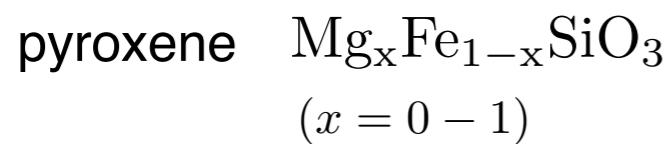

The spectrum of a vibrational transition of a diatomic **gas** molecule, like CO, splits into rotational line which generally group into an R-branch and a P-branch corresponding to rotational transitions with  $\Delta J = 1$  and  $\Delta J = -1$ , respectively.

Molecules in an ice mantle are squeezed in by other molecules and cannot rotate freely, so these branches are suppressed.

# Dust Materials

- Silicates
  - The two main types of silicates in dust are pyroxene and olivine.

[Left] Olivine is the simplest silicate structure, which is composed of isolated tetrahedra bonded to iron and/or magnesium ions. No oxygen atom is shared to two tetrahedra.

[Middle] In pyroxene, silica tetrahedra are linked together in a single chain, where one oxygen ion from each tetrahedra is shared with the adjacent tetrahedron.

[Right] Other types are possible. In amphibole structures, two oxygen ions from each tetrahedra are shared with the adjacent tetrahedra.

In mica structures, the tetrahedra are arranged in continuous sheets, where each tetrahedron shares three oxygens with adjacent tetrahedra.

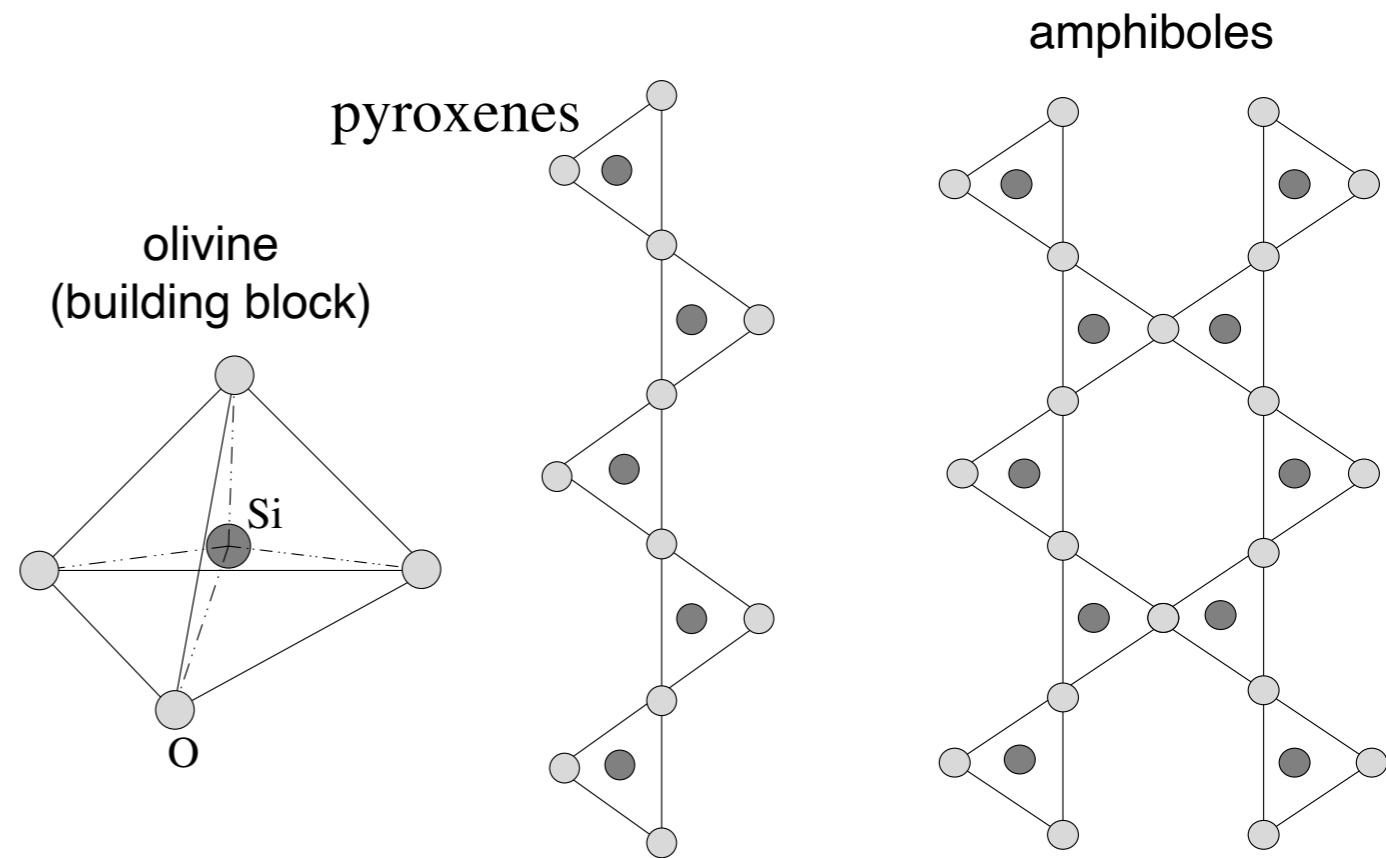

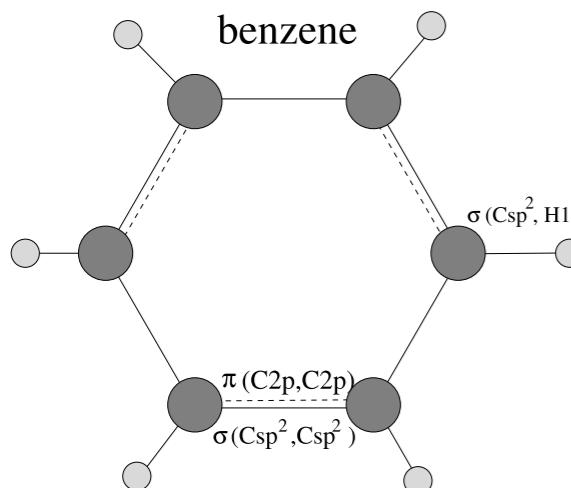

Fig 5.9 Krugel  
 [An Introduction to the Physics of Interstellar Dust]

- The observed interstellar absorption is broad and smooth, quite unlike the highly structured absorption profiles measured for crystalline silicate minerals in the laboratory. It appears that the interstellar material is amorphous rather than crystalline.
- Upper limits can be placed on the fraction of interstellar silicates that are crystalline. Li & Draine (2001) found that not more than 5% of interstellar Si atoms could be in crystalline silicates. Kemper et al. (2005) places a tighter upper limit of 2.2%.
- However, the IR spectra of some AGB stars (de Vries et al. 2010), as well as some comets (Wooden et al. 1999; Comet Hale-Bopp) and disks around T Tauri stars (Olofsson et al. 2009) do show fine structure characteristic of crystalline silicates.

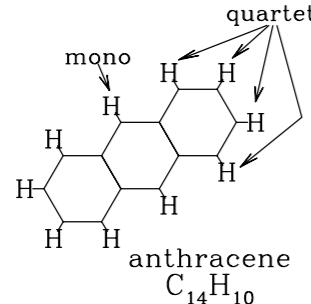

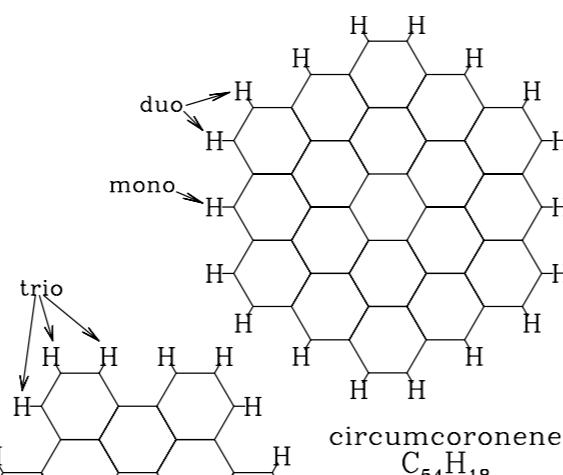

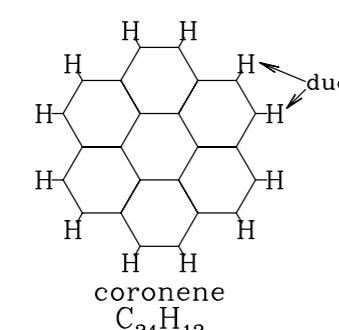

## • Polycyclic Aromatic Hydrocarbons

- The IR emission spectra of spiral galaxies show emission features at 3.3, 6.2, 7.7, 8.6, 11.3, and 12.7  $\mu\text{m}$  that are attributable to vibrational transitions in polycyclic aromatic hydrocarbon (PAH) molecules.
- PAH molecules are planar structures consisting of carbon atoms organized into hexagonal rings, with hydrogen atoms attached at the boundary.

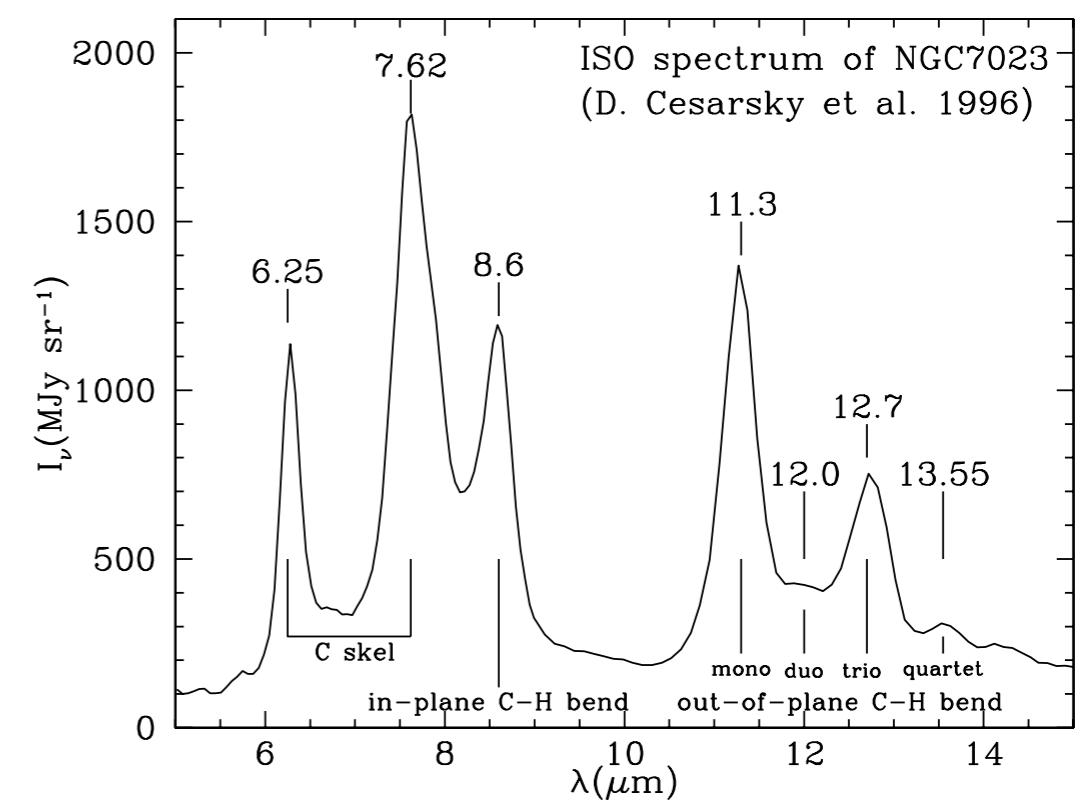

Bezene ring:  
The simplest type of PAHs.

[Fig 5.6 in Krugel]

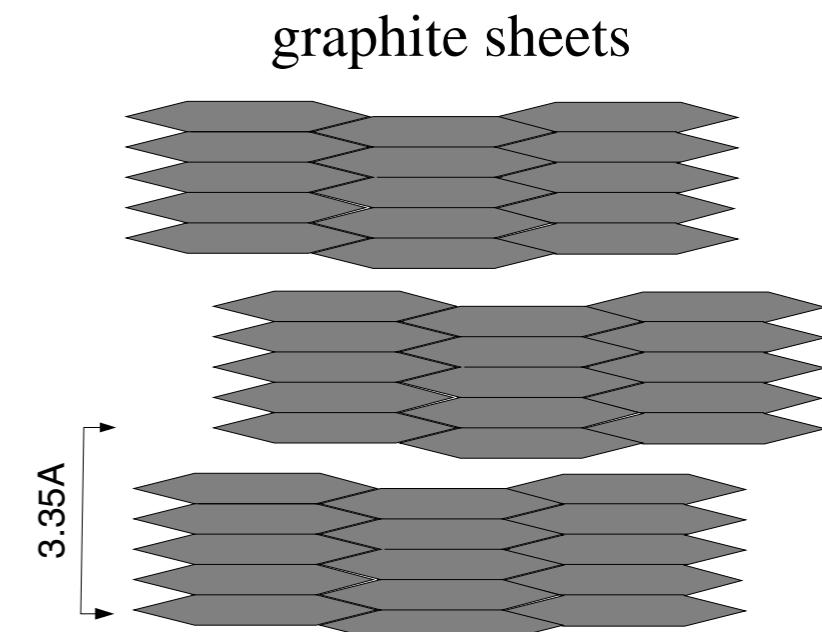

Structure of four PAHs.  
[Fig 23.9 in Draine]

The IR spectrum of the reflection nebula NGC 7023 (Cesarsky et al. 1996)

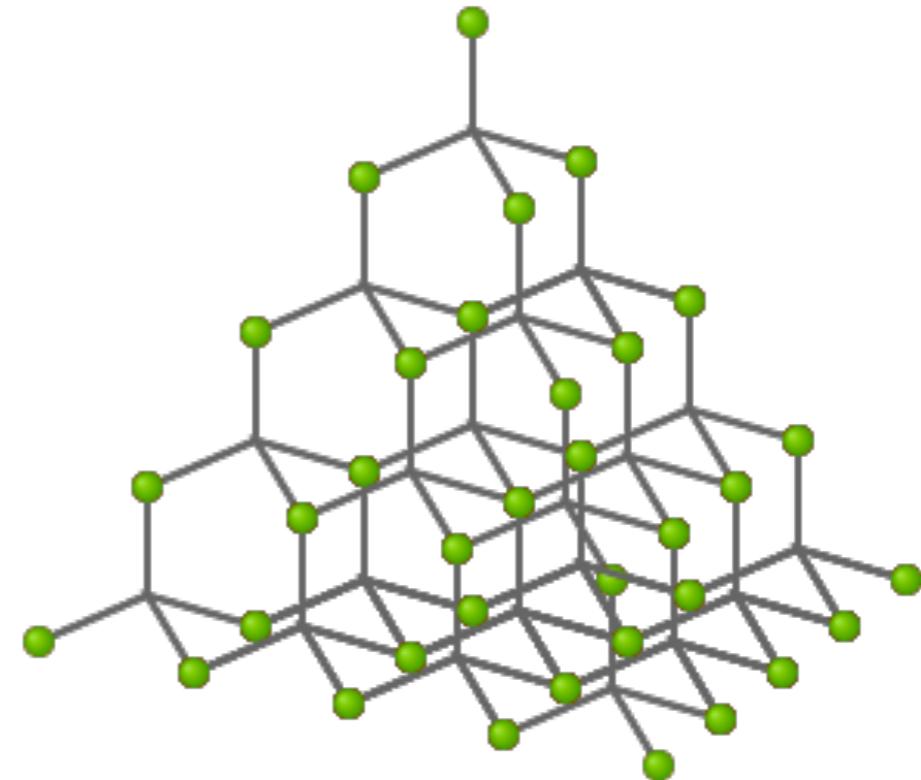

- 
- PAH emission features can account for as much as 20% of the total IR luminosity of a star-forming galaxy.
  - Line identifications:
    - ▶  $3.3\mu\text{m}$  : C-H stretching mode
    - ▶  $6.2$  and  $7.7\mu\text{m}$  : vibrational modes of the carbon skeleton
    - ▶  $8.6\mu\text{m}$  : in-plane C-H bending modes
    - ▶  $11.3$ ,  $12.0$ ,  $12.7$ , and  $13.55\mu\text{m}$  : out-of-plane C-H bending modes, of H atoms at “mono”, “duo”, “trio”, or “quartet” sites, defined by the number of adjacent H atoms.
  - PAH ionization:
    - ▶ A neutral PAH can be photo ionized by the  $< 13.6\text{ eV}$  starlight in diffuse clouds, creating a  $\text{PAH}^+$  cation, and large PAHs can be multiply ionized.
    - ▶ Collision of a neutral PAH with a free electron can create a  $\text{PAH}^-$  anion.
  - The matches between observations and laboratory spectra are always close, but never close enough. This has lead some researchers to suspect that the PAH features arise from complex mixtures of different carriers (mixture of neutral and charged PAHs; “damaged” or “modified” PAHs).
  - The fraction of interstellar carbon that is incorporated into PAH material is uncertain. Based on the observed strength of the PAH emission features, it appears that  $\sim 10\text{-}15\%$  of the interstellar carbon resides in PAHs containing fewer than  $\sim 500$  C atoms.
  - The PAH emission features are excited only in PAHs that are sufficiently small so that absorption of a single optical or UV photon can heat the grain to  $T > 250\text{ K}$ . Additional PAH material may be incorporated into larger grains.

- Graphite
  - Graphite is the most stable form of carbon (at low pressure), consisting of infinite parallel sheets of  $sp^2$ -bonded carbon.
    - ▶ A single (infinite) sheet of carbon hexagons is known as graphene. Each carbon atom in graphene has three nearest neighbors, with a nearest-neighbor distance of  $1.421\text{\AA}$ .
    - ▶ Crystalline graphite consists of regularly stacked graphene sheets, with an interlayer separation of  $3.354\text{\AA}$  and a density of  $2.26 \text{ g cm}^{-3}$ .
    - ▶ The sheets are weakly bound to one another by van der Waals forces.
  - Graphite is a semimetal, with nonzero electrical conductivity even at low temperatures. It is a strongly anisotropic material; the response to applied electric field depends on the orientation of the electric field relative to the “basal plane”.
  - Stecher & Donn (1965) noted that ***small, randomly oriented graphite spheres would be expected to produce strong UV absorption with a profile very similar to the UV bump near  $2175\text{\AA}$ .*** This absorption is due to  $\pi - \pi^*$  transitions in the graphite.
  - The electron orbitals of the C atoms in the interior of a large PAH molecule are very similar to the electron orbitals in graphite. PAHs therefore also have strong absorption near  $2175\text{\AA}$ .
  - Given the abundance of PAHs required to account for the observed IR emission features, ***it now seems possible that the observed  $2175\text{\AA}$  extinction feature may be produced primarily by absorption in PAH molecules, or clusters of PAHs, rather than particles of graphite.***

Graphite structure  
[Fig 5.7 in Krugel]

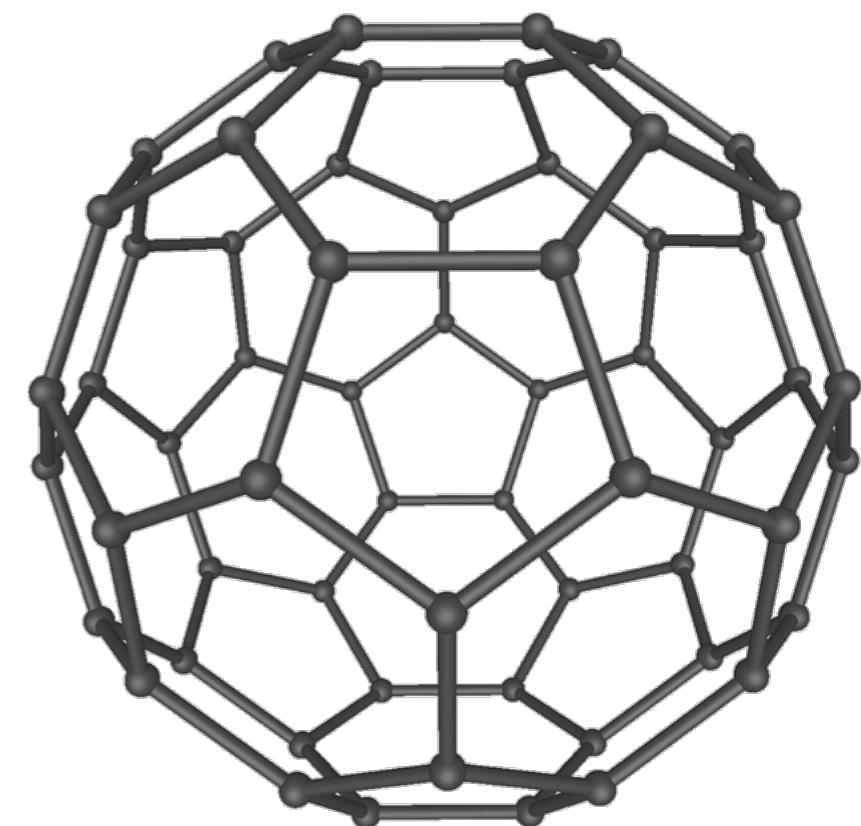

- 
- Nanodiamond
    - Diamond consists of  $sp^3$ -bonded carbon atoms, with each carbon bonded to four equidistant nearest neighbors (enclosed angles are  $109.47^\circ$ ).
    - Diamond nanoparticles are relatively abundant in primitive meteorites. Based on isotopic anomalies associated with them, we know that some fraction of the nanodiamond was of premolar origin.
    - But, its abundance in the ISM is not known.

Structure of diamond.

- Armorphous carbon
  - Armorphous carbon is a mixture of sp<sub>2</sub>- and sp<sub>3</sub>-bonded carbon - one can think of it as a jumble of micro crystallites with more-or-less random orientations. Armorphous carbon is not a well-defined material, and its properties depend on the method of preparation. Armorphous carbon is an insulator.
- Hydrogenated amorphous carbon (HAC)
  - HAC is a class of materials obtained when sufficient hydrogen is present, with H:C ratios ranging from 0.2:1 to 1.6:1 (Angus & Hayman 1988). As with amorphous carbon, the properties of HAC depend on the method of preparation. HAC is a semiconductor.
- Glassy or vitreous carbon
  - This is composed primarily of sp<sub>2</sub>-bonded carbon, but without long-range order, and is another form of solid carbon that is generally considered to be distinct from amorphous carbon. Vitreous carbon is electrically conducting, with a conductivity similar to the conductivity of graphite for conduction in the basal plane.

- 
- Fullerenes
    - Fullerenes are cage-like carbon molecules, including C<sub>60</sub>, C<sub>70</sub>, C<sub>76</sub>, and C<sub>84</sub>, where the carbon is sp<sup>2</sup>-bonded with 3 near-coplanar nearest neighbors, but where a few of the hexagons are replaced by pentagons to allow the surface to close upon itself.
    - C<sub>60</sub> (also known as buckminsterfullerene) is the most stable fullerene.
    - Foing & Ehrenfreund (1994) found DIBs at 9577Å and 9632Å that are consistent with lab measurements of absorption by C<sub>60</sub><sup>+</sup>, but the identification remains tentative, because of failure to detect associated features expected near 9366Å and 9419Å.
    - Sellgren et al. (2010) reported observation of IR emission features at 7.04, 17.4, and 18.9um, that appear to confirm the presence of neutral C<sub>60</sub> in the reflection nebula NGC 7023.
    - Cami et al. (2010) report detection of IR bands of C<sub>60</sub> and C<sub>70</sub> in a young, carbon-rich, planetary nebula.

Buckminsterfullerene

# Dust Theory: cross section and efficiency factors

---

- **Cross Sections:**

- A dust grain has wavelength-dependent cross sections for absorption and scattering. Extinction is the sum of absorption and scattering processes.

$$C_{\text{ext}}(\lambda) = C_{\text{abs}}(\lambda) + C_{\text{sca}}(\lambda)$$

- For a population of dust grains with number density  $n_d$ , the extinction cross section is related to the extinction coefficient and the dust optical depth by:

$$\kappa_\lambda = n_d C_{\text{ext}}(\lambda)$$

$$\begin{aligned} \tau_\lambda &= n_d C_{\text{ext}}(\lambda) L && L = \text{pathlength} \\ &= 1.086 A_\lambda \end{aligned}$$

- **Efficiency Factors:**

- The cross section is often expressed in terms of efficiency factors, normalized to the geometric cross section of an equal-solid-volume sphere:

$$Q_{\text{ext}}(\lambda) = \frac{C_{\text{ext}}(\lambda)}{\pi a^2}, \quad Q_{\text{abs}}(\lambda) = \frac{C_{\text{abs}}(\lambda)}{\pi a^2}, \quad Q_{\text{sca}}(\lambda) = \frac{C_{\text{sca}}(\lambda)}{\pi a^2}$$

$$V = \frac{4\pi}{3} a^3 \quad a = \text{the radius of an equal-volume sphere}$$

- Albedo and Scattering phase function

- The **albedo** is defined by

$$\omega(\lambda) = \frac{\sigma_{\text{sca}}(\lambda)}{\sigma_{\text{ext}}(\lambda)}$$

- Scattering is a function of the scattering angle and thus expressed in terms of the differential scattering cross section:

$$\sigma_{\text{sca}}(\lambda) = \int_0^{2\pi} \int_0^\pi \frac{d\sigma_{\text{sca}}(\theta, \phi; \lambda)}{d\Omega} \sin \theta d\theta d\phi$$

- The **scattering asymmetry factor** is defined by:

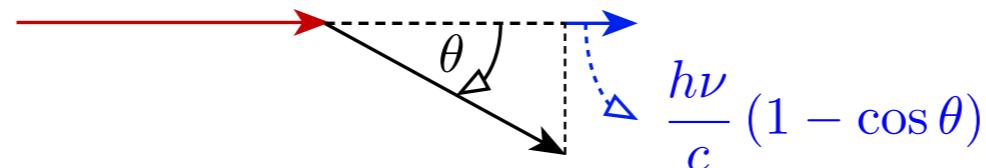

$$g \equiv \langle \cos \theta \rangle = \frac{1}{\sigma_{\text{sca}}} \int_0^{2\pi} \int_0^\pi \cos \theta \frac{d\sigma_{\text{sca}}}{d\Omega} \sin \theta d\theta d\phi$$

- The scattering phase function can be described by the Rayleigh function or Henyey-Greenstein function:

$$\mathcal{P}(\theta) \equiv \frac{1}{\sigma_{\text{sca}}} \int_0^\pi \frac{d\sigma_{\text{sca}}}{d\Omega} d\phi \rightarrow \begin{aligned} \mathcal{P}_{\text{Ray}}(\theta) &= \frac{1}{2} (1 + \cos^2 \theta) & \text{for } \frac{2\pi a}{\lambda} \ll 1 \longrightarrow \langle \cos \theta \rangle = 0 \\ \mathcal{P}_{\text{HG}}(\theta) &= \frac{1}{2} \frac{1 - g^2}{(1 + g^2 - 2g \cos \theta)^{3/2}} & \text{for } \frac{2\pi a}{\lambda} \gg 1 \longrightarrow \langle \cos \theta \rangle = g \end{aligned}$$

- ▶ The Rayleigh scattering is not isotropic, even though  $g = 0$ .
  - ▶ The Henyey-Greenestein phase function is only introduced for computational convenience and has no physical meaning.
- **Radiation pressure cross section:** Electromagnetic radiation exerts a pressure on a grain. A photon that is absorbed deposits its full momentum  $h\nu/c$ . If it is scattered at an angle  $\theta$ , the grain receives (in the forward direction) only the fraction  $1 - \cos \theta$ . Therefore, the cross section for radiation pressure can be written as:

$$\sigma_{\text{rp}} = \sigma_{\text{abs}} + (1 - \langle \cos \theta \rangle) \sigma_{\text{sca}}$$

momentum conservation:  $\mathbf{P}_i = \mathbf{P}_f + \mathbf{P}_{\text{dust}}$

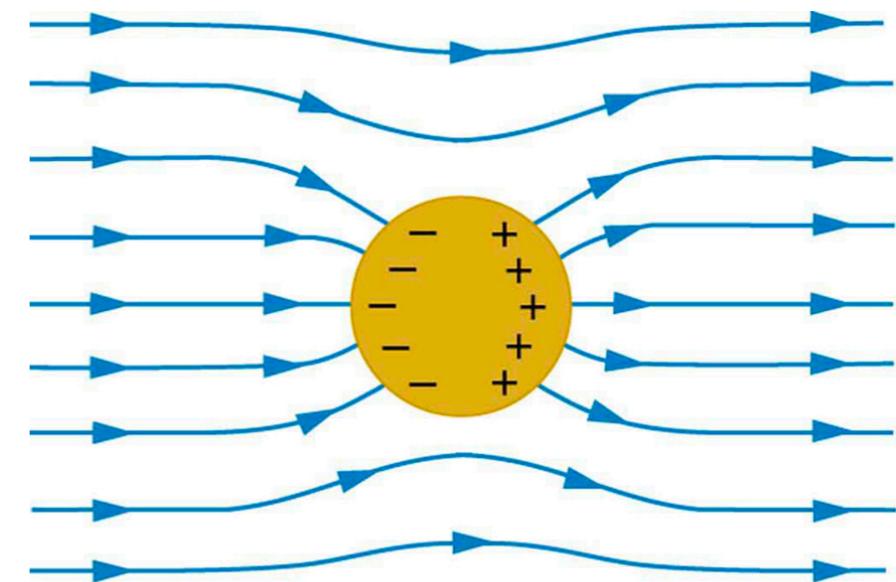

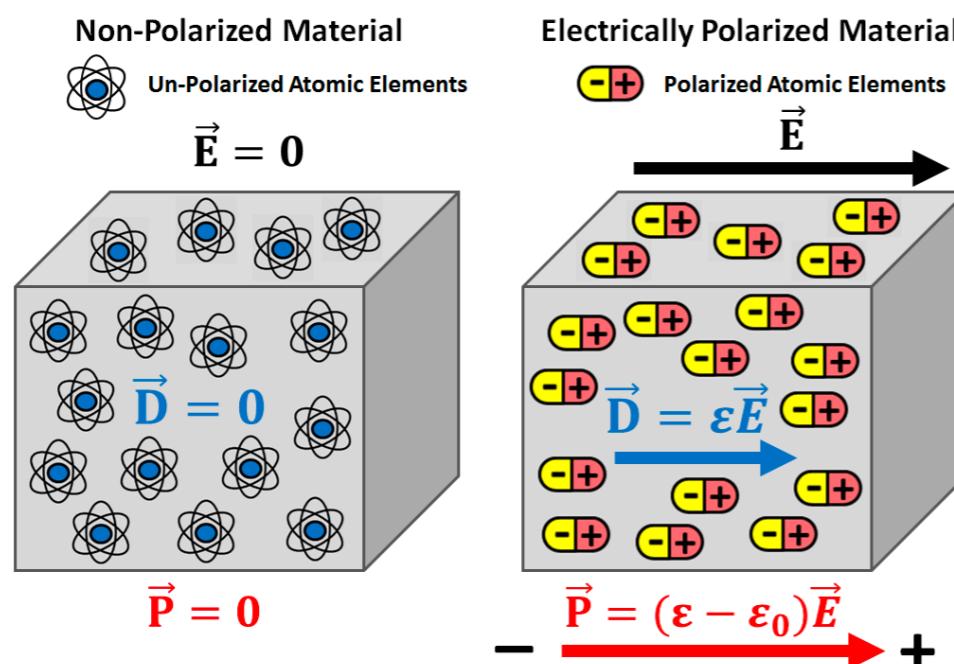

- ▶ The momentum transferred to the grain is

$$\frac{F\sigma_{\text{rp}}}{c}$$

for an incident beam of flux  $F$ .

# Dielectrics and Conductors

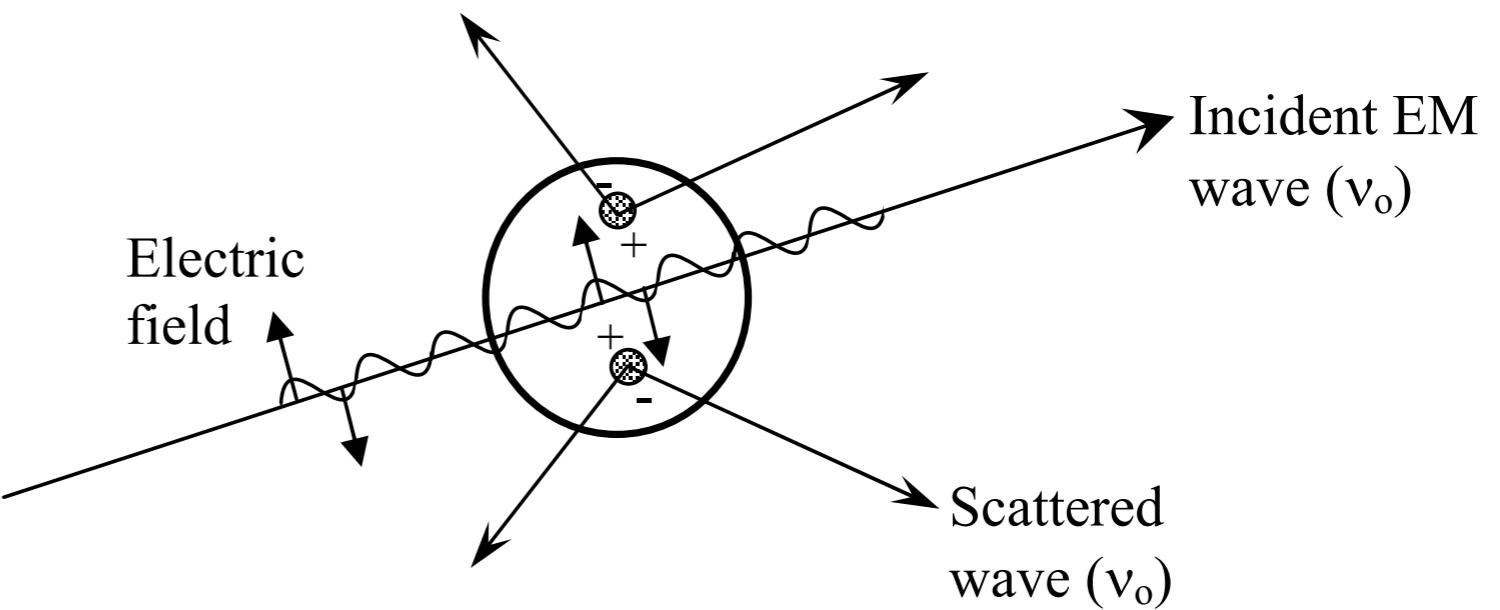

- Materials
  - ▶ **Dielectrics:** Dielectrics are substances which do not contain free charge carriers. They are isolators and no constant current can be sustained within them. Nevertheless, alternating currents produced by a time-variable electric field are possible. In these currents, the charges do not travel far from their equilibrium positions.
  - ▶ **Conductors:** The substances having free charge carriers are called the conductors. When a piece of metal is connected at its ends to the poles of a battery, a steady current flows under the influence of an electric field. When this piece of metal is placed in a static electric field, the charges accumulate at its surface and arrange themselves in such a way that the electric field inside vanishes and then there is no internal current. However, time-varying electric fields and currents are possible.
  - ▶ In the ISM, one finds both dielectric and metallic particles, but the latter are far from being perfect conductors.

# Optical Properties of Grains

- Physical Basis for Scattering and Absorption
  - If an obstacle (which could be a single electron, an atom or molecule, a solid or liquid particle) is illuminated by an electromagnetic wave, electric charges in the obstacle are set into oscillatory motion with ***the same frequency*** as the electric field of the incident wave.
  - We consider the dielectric material to be made up of an infinite number of infinitely small electric and magnetic dipoles whose dipole strengths are proportional to the imposed field strengths. The induced dipoles create their own field or wave in return. The dust particles emits its own field or waves in reaction to the imposed field of waves.

scattering =  
excitation + reradiating

- Accelerated electric charges radiate electromagnetic energy in all directions; it is this secondary radiation that is called ***the radiation scattered*** by the obstacle:

- 
- In addition to reradiating electromagnetic energy, the excited elementary charges may transform part of the incident electromagnetic energy into other forms (thermal energy, for example), a process called ***absorption***.
    - ▶ ***Rayleigh scattering*** (Lord Rayleigh), applicable to small, dielectric (non-absorbing), spherical particles. ==> simple
    - ▶  $|m| \frac{2\pi a}{\lambda} \ll 1$  ( $m$  = the refractive index,  $a$  = radius of the spherical particle)
    - ▶ ***Mie scattering*** (Gustave Mie), the general solution for (absorbing or non-absorbing) spherical particles without a particular bound on particle size. ==> complex
    - ▶ Geometric optics regime: The particle is much larger than the wavelength, so that it can be regarded in the geometric optics regime. This does not mean that its scattering is simple. Reflection on the surface and refraction in the interior can still be quite complex (e.g., light passing through a rain drop), but it can be calculated using ray-tracing through the particle and off the particle's surface.

- In order to calculate scattering and absorption of electromagnetic waves by dust grains, we need to characterize the response of the target material to the local oscillating electric fields.
  - ▶ These enter into the theory through the complex ***index of refraction***,  $m = n_r + i n_i$ , where the real and imaginary part are functions of the wavelength.
  - ▶ Alternatively, the optical properties of a material can be expressed in terms of the ***dielectric function*** (or dielectric constant)  $\epsilon = \epsilon_1 + i\epsilon_2$ . The dielectric constant and the index of refraction are related through.

$$m = n_r + i n_i$$

$$\epsilon = \epsilon_1 + i\epsilon_2$$

$$\epsilon = m^2$$

$$\epsilon_1 = n_r^2 - n_i^2$$

$$\epsilon_2 = 2n_r n_i$$

The electrical conductivity  $\sigma$ , if any, can be absorbed within the imaginary part of the dielectric function.

$$\mathbf{J} = \sigma \mathbf{E}$$

$$\epsilon \rightarrow \epsilon + \frac{4\pi i\sigma}{\omega}$$

- ▶ They are often referred to as optical constants.
- Consider a plane wave traveling in the z direction represented by

$$E = E_0 \exp [i(kz - \omega t)]$$

- ▶ In free space, the wave vector is given by

$$k = \omega/c = 2\pi/\lambda \quad (\lambda = \text{wavelength in vacuum})$$

- ▶ In a material with the index of refraction  $m$ , the wave vector is:

$$k = m\omega/c$$

The electric field becomes:

$$E = E_0 \exp\left(-\frac{n_i\omega}{c}z\right) \exp\left[-i\omega\left(t - \frac{n_r z}{c}\right)\right]$$

Thus, ***the real part of the index of refraction introduces a phase shift*** while the ***imaginary part results in damping***. The power of electromagnetic wave will decrease as it propagates through the material, with

$$|E|^2 \propto e^{-2n_i\omega z/c}$$

The attenuation coefficient will be

$$\kappa = 2n_i \frac{\omega}{c} = \frac{4\pi n_i}{\lambda}$$

- Examples:

- ▶ For transparent substances, the imaginary part of the index of refraction is much smaller than one.

$$m = 1.31 + i(3.1 \times 10^{-9}) \quad \text{pure water ice, } \lambda = 5500\text{\AA}$$

- ▶ For highly reflective substances, the imaginary part of the index of refraction is comparable to or greater than one.

$$m = 0.36 + i2.69 \quad \text{gold, } \lambda = 5500\text{\AA}$$

- ▶ The index of refraction can be strongly dependent on wavelength.
- ▶ Silicon goes from being opaque in the UV to being transparent in the near IR.

The real (blue) and imaginary (cyan) components of the index of refraction for silicon at  $T = 300$  K.
